KEYWORDS
Veterans; Epidemiology; Tuberculosis; Military personnel; Retrospective cohort studies
ABSTRACT

Objective

Tuberculosis was a major cause of morbidity and manpower loss in the Armed Forces during the Second World War. Military control programmes commenced in the 1950s but were initially limited in scope by the many recruits who were already tuberculin positive on enlistment. The aim of our study was to examine whether veterans have an increased risk of tuberculosis compared with non-veterans.

Methods

Retrospective cohort study of 57,000 veterans born 1945-1985, and 173,000 people with no record of military service, resident in Scotland, matched for age, sex and area of residence, using Cox proportional hazard analysis to compare the risk of tuberculosis overall, by birth cohort, length of service and year of diagnosis, and to examine co-morbidities.

Results

Over mean 29 years follow-up, 69 (0.12%) veterans were recorded as having tuberculosis, compared with 267 (0.15%) non-veterans (unadjusted hazard ratio 0.90, 95% confidence intervals 0.69-1.19, p=0.463). Only the 1945-1949 veterans’ birth cohort was at higher risk, unadjusted hazard ratio 1.54, 95% confidence intervals 0.98-2.45, p=0.061, although the difference in risk did not achieve significance. Veterans born from 1950 were at significantly reduced risk of tuberculosis compared with non-veterans after adjusting for deprivation, hazard ratio 0.67, 95% CI 0.47-0.95, p=0.026. The commonest co-morbidities were smoking- and alcohol-related disease. The risk of co-morbid hepatitis B or C was very low, in both
veterans and non-veterans. No length of service was associated with an increased risk of tuberculosis in comparison with non-veterans.

**Conclusion**

Scottish veterans born before 1950 are at moderately increased risk of tuberculosis compared with age, sex and geographically matched civilians with no record of service, although the difference is not statistically significant. Scottish veterans born from 1950 show a reduction in risk compared with civilians. Tuberculosis should be considered in the differential diagnosis of respiratory disease in the older veteran.
KEY/EDUCATIONAL MESSAGES

- Tuberculosis is known to have been a major cause of morbidity among military personnel during the Second World War and earlier.

- Scottish veterans born before 1950 are at moderately increased risk of tuberculosis compared with non-veterans.

- Veterans born from 1950 are at lower risk of tuberculosis than non-veterans, providing evidence for the effectiveness of military control measures.

- Tuberculosis should be considered in the differential diagnosis of respiratory disease in the older veteran.
INTRODUCTION

During the 19th century, tuberculosis was the leading cause of death and disability in the UK, although the overall number of deaths fell in the second half of the 19th and early 20th centuries.[1] Between 1952 and 1985, the incidence of tuberculosis reduced in the general US population, before starting to increase again.[2] In the UK, cases rose by 46% between 1998 and 2009, with much of the increase arising in people born in countries having a high burden of tuberculosis [3] and are now deemed unacceptably high, at 12.3 per 100,000 in 2013, compared with other countries.[4] Among UK-born people, the incidence is around 4 cases per 100,000 people per year, compared with 70 per 100,000 in people born in high-risk areas overseas.[3, 4] Other risk factors for tuberculosis include smoking, heavy alcohol use, poverty, and homelessness, as well as immunosuppression, especially in consequence of diseases such as HIV.[2] Diabetes is also an independent risk factor,[5] and may account for some of the recent increase in incidence.

Military personnel may be at increased risk of tuberculosis as a result of shared accommodation,[6] increased prevalence of smoking,[7, 8] alcohol consumption,[9] or as a result of military service in high-risk areas. In the late 19th century, tuberculosis was a major cause of manpower loss, accounting for around 17% of medical discharges from the British Army in 1891 (300 per 100,000 strength per year), and was the commonest disease-related cause of discharge from service. Although the rate fell to an average of 150 per 100,000 during the early 20th century with improvements in public health, it continued at around the same level until the 1950s.[10] The Second World War saw a heavy burden of tuberculosis; between September 1939 and September 1951, 60,645 individuals were discharged from the Armed Forces and awarded a pension for tuberculosis which was considered to have
been either caused by or aggravated by war service.[11] With the introduction of effective treatment and a control programme for tuberculosis in the Armed Forces, the rate of medical discharge fell throughout the late 1950s and 1960s, and by the end of the millennium, discharge for this reason had become rare.[10] There have been a number of changes in Service immunisation policy to reflect changing national guidelines and risk assessment. Currently, all recruits from high incidence countries (defined as incidence ≥40 per 100,000 per year) are screened in accordance with UK national guidelines, [12] whilst all others are offered Mantoux testing and, if necessary, BCG vaccine unless they have evidence of previous immunisation (either documentary or a BCG scar). Catch-up testing and immunisation is offered to deployable personnel under the age of 36 years who have not previously been immunised.[13] This study examines the impact of tuberculosis in the current generation of military veterans, many of whom served prior to the full implementation of control measures.
METHODS

The Scottish Veterans Health Study is a retrospective cohort study comprising all 56,570 military veterans (defined as individuals having at least one day’s service in the UK Armed Forces [14]) born between 1945 and 1985 who were registered with NHS Scotland both prior to military service and following discharge, and a comparison group of 172,753 individuals with no record of military service, matched by age, sex and postcode sector of residence (mean population 5,000). Participants were identified via their electronic NHS registration records, which provided demographic information as well as the dates of entering and leaving military service. These records were linked, at the individual level, to routine hospital admissions data (Scottish Morbidity Record SMR01) and death certificates to provide follow-up information on incidence of tuberculosis, co-morbidities and mortality. Information was available for follow-up events that occurred between 1 January 1981 and 31 December 2012 inclusive. The cohort and methods have been described in detail elsewhere.[15] The data extract was pseudo-anonymised, and approval for the study was granted by the Privacy Advisory Committee of the Information Services Division of NHS Scotland.

A measure of deprivation is available from the Scottish Index of Multiple Deprivation (SIMD), which is based on 6,505 datazones, derived from postcode of residence, each having a mean population of 800. Deprivation status is calculated from information on income, employment, health, education (including skills and training), housing, crime, and access to services.[16] The SIMD has been used to derive quintiles of socioeconomic status for the
Scottish population; ranging from 1 (most deprived) to 5 (least deprived). The cohort participants were categorised according to these quintiles using postcode of residence.

Cox proportional hazard models were used to examine the association between veteran status and cumulative risk of tuberculosis, using age as the time dependent variable, age at first record of tuberculosis as the failure time and death (if no record of tuberculosis) as the censor time. The association with selected co-morbidities in veterans and non-veterans with a diagnosis of tuberculosis was also examined. Hazard ratios and p values were calculated and the a priori rejection level was set at 0.05. Proportionality was tested using methodology based on Schoenfeld residuals.[17] The models were run univariately and then repeated adjusting for the confounding effect of deprivation. The analyses were repeated by year of birth, stratified in 5-year bands, to examine birth cohort effects. Further subgroup analyses were undertaken to examine the effect of length of service, in categories reflecting common UK lengths of military engagement. Mortality in those with a diagnosis of tuberculosis was examined by cause. All analyses were performed using Stata® v12.1 and Excel® 2007.
RESULTS

After data cleansing, 56,205 (99.3%) veterans and 172,741 (99.9%) non-veterans were included in the analysis. The mean period of follow-up was 29.3 years, and there was a total of 6.7 million person years of follow-up among veterans and non-veterans combined. During the period of follow-up, 69 (0.12%) veterans had a diagnosis of tuberculosis compared with 267 (0.15%) non-veterans. The reduction in risk in the veterans was not statistically significant in the unadjusted model, hazard ratio (HR) 0.90, 95% confidence intervals (CI) 0.69-1.19, p=0.463. After adjusting for deprivation, the reduction in risk in veterans was greater but remained non-significant, HR 0.85, 95% CI 0.65-1.12, p=0.247. The Nelson-Aalen cumulative hazard plot confirmed the lower risk in veterans, using a landmark age of 20 years to exclude those with a history of childhood tuberculosis which may have precluded military service (Figure 1).

When analysed by birth cohort, only veterans born between 1945 and 1949 showed an increased risk of tuberculosis (Figure 2), although this was non-significant in the unadjusted model, HR 1.54, 95% CI 0.98-2.45, p=0.061, and remained non-significant after adjusting for deprivation. Veterans in each of the more recent birth cohorts, 1950 onwards, were at lower or similar risk of tuberculosis compared with non-veterans; the overall reduction in risk in veterans born from 1950 was statistically significant after adjusting for deprivation, HR 0.67, 95% CI 0.47-0.95, p=0.026.

Common co-morbidities included alcoholic liver disease, affecting 7 (10.1%) of the veterans and 25 (9.4%) of the non-veterans with tuberculosis; chronic obstructive pulmonary disease, affecting 19 (27.5%) veterans and 52 (19.5%) non-veterans; lung cancer, recorded in 5 (7.2%) veterans and 4 (1.5%) non-veterans; and any mental health disorder, affecting 8
(11.6%) veterans with tuberculosis and 28 (10.5%) non-veterans. Only for lung cancer did the difference in risk achieve statistical significance, OR 4.83, 95% CI 1.33-17.95, p=0.008. The number of either veterans or non-veterans with tuberculosis who had a diagnosis of either hepatitis B or hepatitis C was very low. Five (7.2%) veterans and 18 (6.7%) non-veterans also had a recorded diagnosis of diabetes.

Analysis of year of first record of tuberculosis, using a kernel density plot (Figure 3) showed a gradual increase in cases throughout the 1980s and 1990s, reaching a peak around the year 2000 for both veterans and non-veterans, before starting to fall. There was a biphasic pattern, with a small peak in the mid-1980s, in both veterans and non-veterans although that peak was higher in the non-veterans.

Analysis by length of service showed that longer service was associated with the lowest risk of tuberculosis, but overall there was no increase in risk associated with any length of service, including Early Service Leavers, in comparison with the entire non-veteran group.

By the end of follow-up, 27 (39.1%) veterans with tuberculosis had died, compared with 81 (30.3%) non-veterans. Seven non-veterans with tuberculosis, but only one veteran, had a cause of death coded as alcohol dependence syndrome; no other cause of death predominated in either group.
DISCUSSION

Main findings

Evidence from the Scottish Veterans Health Study has demonstrated that the oldest veterans, born 1945-1949, were more likely to develop tuberculosis than people with no record of service matched for age, sex and area of residence, although the reverse was true for veterans born from 1950 onwards. Small numbers of cases precluded statistical significance at subgroup level, other than for all veterans born from 1950, where the reduction in risk was significant. Examination of co-morbidities indicated that smoking and alcohol were risk factors for tuberculosis in both veterans and in non-veterans, but that the magnitude of association for smoking-related disease was higher in veterans. There was no evidence that drug abuse was a risk factor, based on the finding of a lack of association with hepatitis B or C.

Historical background

In 1882, Robert Koch identified the causative organism for tuberculosis as *M. tuberculosis*, and by 1921 human vaccination trials commenced using a vaccine based on an attenuated form of the related *M. bovis*, named Bacillus Calmette-Guérin (BCG) after the researchers who had developed it.[18] Early vaccination programmes targeted infants but in 1953, the UK commenced routine administration of BCG vaccine to all tuberculin-negative 13-year old children whose parents consented. Because of the impact of tuberculosis in the Armed Forces and the risk of cross-infection in shared accommodation, a sub-committee of the Research Committee of the British Tuberculosis Association had been convened in November 1951 to consider the case for BCG vaccination of Service entrants.[11] They
identified important practical difficulties; 63.5% of 18-year-olds were already tuberculin-positive, and the rapid dispersal of recruits made it impractical to meet the timetable which would be required for tuberculin testing, reading and vaccination of 220,000 men per year (150,000 National Servicemen and 70,000 regular recruits). The vaccine was also unstable and had to be administered within 48 hours of receipt at a military establishment, presenting major logistic difficulties and a risk of wastage.[19]

Military BCG vaccination had already commenced covering certain categories of medical and nursing staff in 1951 [20] and Nepalese Gurkha soldiers in 1952.[21] A scheme for extending the programme to all recruits was proposed, linked to the Mass Miniature Radiography (MMR) screening programme which by then was reaching 85% of all recruits (although the quality of some films gave rise to concern), noting that 50-60% would be likely to prove tuberculin positive for some years to come. At that time it was generally considered that a positive tuberculin test indicated ‘natural immunity’, usually acquired through exposure to M. bovis in milk, but a Medical Research Council report in 1957 remarked, with evident surprise, that there was a high incidence of active tuberculosis developing within the subsequent two and a half years in those recruits with a tuberculin reaction in excess of 15mm, and suggested that it might be necessary to exclude such personnel from service.[11] It was agreed that post-vaccination re-testing could be omitted as other evidence had been presented showing a high seroconversion rate. The Ministry of Labour and National Service considered that youths over 16 years of age were normally sufficiently mature to consent to testing and immunisation without the need for parental consent. The future impact of school-based immunisation was noted, with the proviso that it was not yet known whether immunity would wane. The slow development of immunity
following BCG administration was also considered to present a case for the establishment of immunity prior to the commencement of service. The authors of the report recommended that both MMR screening and BCG vaccination were required in order to effect a substantial reduction in the incidence of tuberculosis in the Armed Forces, and that the two were complementary. They recommended a pilot scheme for a national BCG vaccination programme in Service recruits. Implementation of the scheme, together with routine chest radiography on entry and 4-yearly thereafter (the latter being discontinued in the early 1980s), and better treatment of active cases, resulted in a rapid fall in active military disease although latent disease persisted for some time.

Factors contributing to high levels of tuberculosis in military personnel in earlier years included population mixing in a group which already had a high background prevalence, shared living accommodation, travel,[22] and stress,[23, 24] all of which can contribute to cross-infection or reactivation of latent disease. Those living and working in a closely-confined environment such as on board a warship were especially at risk.[25] With the length of ‘other rank’ (non-commissioned) service ranging up to 22 years, or longer for those permitted to enter the Long Service list, and officers able to serve to age 55 years, there were still many people serving in the 1970s who had entered the Armed Forces prior to the introduction of the immunisation programme. They may have inadvertently acted as a reservoir of infection within the military community, many years prior to the recognition of the importance of, and ability to reliably diagnose, latent tuberculosis. Disease in these older military personnel is consistent with the findings of this study; those born in later years, who joined the Armed Forces after most of those who had entered service prior to the control programme had left, showed no greater risk than individuals who have never
served. Published studies on the incidence or prevalence of tuberculosis in veterans are sparse but Levine reports an incidence of hospitalisation for tuberculosis 1.3 times higher in US veterans than in age-matched US males between 1984 and 1993 (29.1/100,000 compared with 22.1/100,000).[26] However, the veterans were patients receiving care from Veterans Administration Medical Centres (VAMC), access to which is limited to the lowest income group (11.3% of veterans), who may have been at higher risk of tuberculosis for reasons other than their veteran status; the author notes co-morbidity with AIDS (up to r=0.8, p<0.001). In a major Australian study of mortality in Korean War veterans covering 50 years of observation, the SMR for tuberculosis was 0.95 (95% CI 0.40-1.49) after excluding unknowns but this was based on only 12 deaths (out of a total of 7,514 deaths).[27]

Implications for the future

Although the implementation of effective control measures over the last 40 years means that recent veterans are at no increased risk, the high burden of tuberculosis faced by British Service personnel up to the 1970s, when those born 1945-1949 were serving, means that there are many older veterans still living who were treated for, and/or medically discharged for, tuberculosis during their service, or who lived with latent disease throughout their service. As immune function becomes impaired in this cohort though age, disease or immunosuppressive treatment, reactivation of latent disease remains a risk, and diagnosis may be more difficult owing to atypical presentation in this age group.[28] Although World War 2 veterans were out of scope for this study, it is likely that their risk is even higher in view of the prevalence of tuberculosis, and lack of control measures, during the war years.

Strengths and limitations
The strengths of the present study are that it was based on a large cohort covering the whole of Scotland with up to 30 years follow-up. The use of record linkage to analyse individual level data directly derived from health records allowed a robust cohort study design to be employed. The results were able to be matched or adjusted for potential confounders including deprivation. It was possible to do subgroup analysis by birth cohort, year of diagnosis and length of service, contributing to the understanding of factors influencing veterans’ health.

The major limitation of the study is that although the diagnoses were taken from hospital admission and death records, and are therefore likely to be reliable in respect of those events occurring within Scotland, many cases of tuberculosis are managed in an outpatient setting, especially in more recent years. The assumption has therefore been made that there are no systematic differences in the likelihood of admission or death between veterans and non-veterans, other than the incidence and severity of disease, and that the relative magnitude of deaths and hospitalisations equates to the relative magnitude of total cases. Some loss to follow-up of subjects is likely to have occurred due to migration away from Scotland. Such losses could not be quantified and the assumption has been made that there was no systematic difference in this respect between veterans and non-veterans.

There were no follow-up data prior to the start of linked health data collection in Scotland from 1 January 1981. For those who are military veterans, we have not been able to link to in-service health or service records and thus tuberculosis occurring during service will not have been captured until the individual left the service and received NHS care. Because the dataset was derived from demographic, vital record and hospital admissions data, no
information was available on personal lifestyle risk factors such as smoking or alcohol intake. Therefore, we were unable to directly analyse the impact of these factors or adjust for them. Veterans with Reserve service only could not be identified from NHS records and were therefore included amongst the non-veterans; this would have had the effect of reducing any observed differences between veterans and non-veterans.
CONCLUSION

Scottish veterans born before 1950 are at moderately increased risk of tuberculosis compared with age, sex and geographically matched civilians with no record of service, although the difference is not statistically significant. For those born from 1950 onwards, who served after the implementation of control measures in the Armed Forces and after the majority of those who had joined prior to the control programme had left the Services, there is a significant reduction in risk compared with civilians after adjusting for deprivation. Older veterans are at risk of reactivation of latent disease. Tuberculosis must not be overlooked in the differential diagnosis of respiratory disease in the older veteran.
