Abstract

Background

Clinical translation of immunohistochemistry (IHC) biomarkers requires reliable and reproducible cut-offs or thresholds for interpretation of immunostaining. Most IHC biomarker research focuses on the clinical relevance (diagnostic, prognostic or predictive utility) of cut-offs, with less emphasis on observer agreement using these cut-offs. From the literature, we identified three commonly used cut-offs of 10% positive epithelial cells, 20% positive epithelial cells and moderate to strong staining intensity (+2/+3 hereafter) to use for investigating observer agreement.

Materials and Methods

A series of 36 images of microarray cores stained for four different IHC biomarkers, with variable staining intensity and percentage of positive cells, was used for investigating inter- and intra-observer agreement. Seven pathologists scored the immunostaining in each image using the three cut-offs for positive and negative staining. Kappa statistic was used to assess the strength of agreement for each cut-off.

Results

The inter-observer agreement between all seven pathologists using the three cut-offs was reasonably good, with mean $\kappa$ scores 0.64, 0.59 and 0.62.
respectively for 10%, 20% and +2/+3 cut-offs. A good agreement was observed for experienced pathologists using the 10% cut-off and their agreement was statistically higher than for junior pathologists (p=0.02). In addition, the mean intra-observer agreement for all seven pathologists using the three cut-offs was reasonably good, with mean $\kappa$ scores 0.71, 0.60 and 0.73 respectively for 10%, 20% and +2/+3 cut-offs. For all three cut-offs, a positive correlation was observed with perceived ease of interpretation (p<0.003). Finally, cytoplasmic-only staining achieved higher agreement using all three cut-offs than mixed staining patterns.

**Conclusions**

All three cut-offs investigated achieve reasonable strength of agreement modestly decreasing inter and intra-observer variability in IHC interpretation. These cut-offs have previously been used in cancer pathology and this study provides evidence that these cut-offs can be reproducible between practising pathologists.

**Keywords**

Observer agreement, Kappa, immunohistochemistry, biomarker, cut-off
**Introduction**

The use of immunohistochemistry (IHC) biomarkers for clinical decision making is an important research field with significant translational potential. A multitude of biomarkers for a variety of cancers is available and a large literature exists on novel biomarker discovery, but only a minority impact upon patient care. Amongst other reasons, one barrier to clinical translation of biomarkers is the lack of a standardised cut-off or threshold for interpretation of IHC staining\(^1,^2\).

Evaluation of immunostaining is important in translational studies assessing biomarker expression for diagnostic, prognostic or predictive purposes. Biomarker expression assessment usually employs a continuous or ordinal scale; but for meaningful clinical use it is usually dichotomised and a cut-off established for assigning a patient into either positive/negative expression category or high/low expression category \(^3\). In addition, for some biomarkers, more than two categories may be required for example the ‘Allred score’ for estrogen receptor positivity \(^4\). For clinical translation, there are two main issues in the development and application of a standardised cut-off for IHC biomarkers. One is the identification of an appropriate cut-off that provides suitable sensitivity/specificity for diagnostic biomarkers or that stratifies patients based on survival and response to treatment for prognostic and predictive biomarkers respectively. The other issue is to assess the inter- and intra-observer agreement in the interpretation of a cut-off threshold. One potential strategy to address the former is the use of a receiver operating characteristics (ROC) curve that can
help to identify an appropriate cut-off \(^1,^5\). The latter issue can be answered by assessing the level of agreement between pathologists \(^6^-^8\).

There is currently no standardized cut-off for diagnostic IHC biomarkers. Most of the reported cut-offs are purposive that best fit cancer or normal groups. These cut-offs are based on the intensity of staining or percentage of positive cells or on a combination of both intensity and percentage in terms of immunoreactive scores, H scores and “quick” scores \(^7,^9^-^13\).

Two widely used cut-offs reported in the literature for IHC diagnostic biomarkers are positive/negative staining (e.g. p16/Ki-67 staining for the diagnosis of cervical intra-epithelial neoplasia 3) and 10% positive epithelial cells (e.g. a panel of napsin A, TTF 1, CK 5, and p63 in differentiating adenocarcinoma from squamous cell carcinoma of the lung) \(^14^-^19\). Other reported cut-offs are: more than 30% cells with uniform, intense membranous staining of invasive tumour cells for human epidermal growth factor receptor 2 (HER2) (positive HER2 staining in breast cancer) \(^20\); and more than 5% positive tumour cells for CK 7 and CK 20 (differential diagnosis in metastatic carcinoma of unknown origin) \(^21\).

These scoring systems and cut-offs have been adopted for research purposes. Some of them are used in clinical practice; but studies looking at their reproducibility between pathologists are few. A cut-off should be both clinically relevant and easily interpretable by pathologists. There is a tendency to focus more on the clinical relevance of the cut-off for a biomarker with less focus on the level of agreement between pathologists when they use it for scoring purposes \(^6,^22\). Inter- and intra-observer variation of a cut-off is infrequently
analysed despite the fact that it is recognised as a potential barrier to clinical translation.

We selected three cut-offs for investigation based on our diagnostic IHC work and the wider IHC literature. These cut-offs are 10% positive epithelial cells (10% hereafter), 20% positive epithelial cells (20% hereafter) and moderate to strong staining intensity with any proportion of positive cells (±2/±3 hereafter) 8,14,17,23-. These cut-offs are clinically relevant and we postulated that they are easily interpretable and reproducible amongst pathologists. The aims of the current study were to investigate the cut-offs (10%, 20% and ±2/±3) for inter- and intra-observer agreement; and to explore factors influencing agreement between pathologists for IHC cut-offs.
Materials and Methods

Immunohistochemistry images and participants

A series of 36 images of pancreatic ductal adenocarcinoma (PDAC) tissue microarray cores for four diagnostic IHC biomarkers (nine images each from KOC, maspin, mesothelin and S100P) were used for this study. These cores have previously been studied for diagnostic utility. These cores were carefully selected for each biomarker based on a variable range of staining intensity and proportion of positive cells. Some cores with no immunostaining were also included. The purpose of using images from one type of tumour i.e. PDAC was to allow the observers to concentrate on the immunostaining cut-offs rather than interpreting the morphology of different tumours. KOC expression was cytoplasmic; maspin has both cytoplasmic and nuclear expression but the pathologists were asked to score only cytoplasmic staining for maspin and disregard nuclear staining; mesothelin expression was cytoplasmic and/or membranous; and S100P expression was cytoplasmic and/or nuclear. Seven pathologists (three experienced pathologists and four junior pathologists) participated in the study. Experienced pathologists have clinical pathology experience of more than 15 years, while junior pathologists have 3-7 years of experience. All pathologists were sufficiently trained to evaluate pancreatic tumours. Pathologists were coded as A, B, C, D, E, F and G. Ethical approval has been granted by the North Glasgow University Hospitals NHS Trust Ethics Committee and by the National Health Service Greater Glasgow and Clyde Ethics Committee. This ethics approval includes the use of archival pathology
specimens, where the patients were not given the opportunity to donate their tissue.

**Scoring the IHC cut-offs**

The 36 images were shown via projection on Powerpoint, and were arranged based on biomarkers with reference staining intensities (weak, moderate, severe) provided at the start for each biomarker. A scoring sheet with instructions on scoring was prepared with the help of pathology colleagues (Supplementary Table 1). All the participating pathologists participated in one session for the inter-observer part of the study. After a short presentation (5-10 min) on the purpose of this study, the scoring sheets were distributed between all seven pathologists. Each image was shown for one minute. The pathologists were asked to interpret the immunostaining of each image for the three cut-offs as a binary categorical variable, “present” or “absent”. The three cut-offs were: 10%, 20% and +2/+3 cut-offs. For example, a 10% cut-off is “present” when more than or equal to 10% epithelial cells are positive in the desired subcellular compartment and is “absent” when fewer than 10% epithelial cells are positive. Each core was also recorded as being easy (1) or challenging (2) to score.

All seven pathologists participated in the intra-observer part of the study three weeks after the inter-observer session. The tissue core images shown were the same, but arranged in a different order to minimise recall bias.
Statistics and data analysis

We used kappa (κ) scores as a measure of the strength of agreement between pathologists for all three cut-offs. Kappa scores reflect the strength of agreement between observations, adjusted for chance agreement, and can range from 0 to 1. We used the standards suggested by Landis and Koch for the interpretation of strength of agreement. Kappa scores are shown in six categories from 0-1 and each category is colour coded (Supplementary Table 2).

Inter-observer agreement: to determine inter-observer agreement for each of the three cut-offs, each pathologist’s interpretation of immunostaining was compared with that of the other pathologists in a pair-wise manner. 21 inter-observer (AB, AC, AD and so on...) κ scores were generated for each of the three cut-offs (10%, 20% and +2/+3). Finally a mean inter-observer κ score for each cut-off was used as a measure of strength of agreement between pathologists.

Impact of pathologists’ experience and antibody staining pattern on inter-observer agreement: for each cut off, mean inter-observer κ scores were calculated for experienced pathologists and for junior pathologists and then compared. The staining pattern was noted for the antibody used in each slide and mean k scores calculated for each staining pattern. The aim was to determine if the pathologists tend to have more agreement for a particular staining pattern (cytoplasmic, nuclear and/or membranous).

To determine whether these three cut-offs are statistically different from each other, the paired sample t test (for large sample size) and Wilcoxon signed
ranked test (for small sample size) were used to compare the pairwise $k$ scores. To determine which cut-off is most easily scored, these three cut-offs as predictor variables were put in a linear regression model against perceived ease of scoring as a dependent variable.

Intra-observer agreement: to determine reproducibility of these three cut-offs, kappa scores were generated comparing scoring and re-scoring of the same image arranged in different orders three weeks apart for each pathologists. Kappa scores were generated for all seven pathologists (A-A, B-B, C-C, D-D, E-E, F-F and G-G) using the three cut-offs. Seven intra-observer agreements were generated for each cut-off. A mean intra-observer $\kappa$ score for each cut-off was then used as a measure of strength of agreement.

A $p$ value <0.05 was considered statistically significant. SPSS version 21 was used for statistical analyses.
Results

Taken together, 1512 evaluations were made in the inter- and intra-observer sessions by the pathologists. The average time for interpretation of an image was roughly 30-45 seconds. Results are divided into three parts: inter-observer agreement; perceived ease of scoring; and intra-observer agreement.

Inter-observer agreement

All seven pathologists

The mean inter-observer $\kappa$ scores were 0.64, 0.59 and 0.62 for 10%, 20% and $+2/+3$ cut-offs respectively (Table 1). The mean $\kappa$ score agreement for 10% and $+2/+3$ cut-offs is in the ‘substantial’ agreement category and for the 20% cut-off is in the ‘moderate’ agreement category. However, the $\kappa$ score agreements between the three cut-offs were not statistically different from each other (Supplementary Figure 1).

Figure 1 shows examples of IHC images used in this study. Images with low observer agreement have either weak staining intensity, or the proportion of positively stained cells is lower compared to images with high level agreement. In fact, tissues with both strong staining intensity and a higher percentage of positive cells have higher agreement regardless of the biomarker and staining pattern.
In summary, the inter-observer agreements between all seven pathologists for the three cut-offs were reasonably good. In addition, the agreements for the cut-offs were not statistically different from each other.

**Impact of pathologists’ experience on inter-observer agreement**

The mean inter-observer $\kappa$ scores for experienced pathologists were 0.81, 0.70 and 0.55 for 10%, 20% and +2/+3 cut-offs respectively (Table 2A). The mean inter-observer $\kappa$ scores for junior pathologists were 0.61, 0.60 and 0.73 for 10%, 20% and +2/+3 cut-offs respectively (Table 2B). The agreement on 10% cut-off is statistically higher for the experienced pathologists than the junior pathologists ($P=0.02$, Mann-Whitney U test). However, no statistically significant difference between experienced and junior pathologists was observed for 20% and +2/+3 cut-offs.

In summary, a higher level of agreement was observed for experienced pathologists using 10% cut-off and this was statistically higher than junior pathologists.

**Impact of antibody staining pattern on inter-observer agreement**

In the images studied, there were three staining patterns: cytoplasmic only staining; cytoplasmic and/or nuclear staining (CN); and cytoplasmic and/or membranous staining (CM).

The mean $\kappa$ scores for cytoplasmic only staining were higher than the other staining patterns. More specifically, a statistically higher agreement for
cytoplasmic only staining was observed in the following scenarios: cytoplasmic compared to CN category using +2/+3 cut-off; and cytoplasmic compared to CM category using 20% and +2/+3 cut-offs.

Moreover, a statistically higher agreement for CN staining was observed in the following scenarios: CN compared to CM category using 20% and +2/+3 cut-offs. No statistically significant difference between different staining patterns was observed for the 10% cut-off (Table 3).

In summary, there is more inter-observer agreement for cytoplasmic only staining followed by CN and CM. Finally the 10% cut-off appears to yield good inter-observer agreement irrespective of the staining compartment of cell.

**Relationship between cut-offs and perceived ease of scoring**

A positive correlation was observed between all three cut-offs and perceived ease of scoring (p<.0001). However, in a multivariate analysis the 10% cut-off (β=0.41, p<0.001) was more easily scored as compared to the +2/+3 cut-off (β=0.38, p=0.001) or the 20% cut-off (β=0.34, p=0.004) (Table 4).

Interestingly, the pattern emerging from this correlation, that 10% is relatively more easily scored, followed by +2/+3 and 20%, supports the mean inter- and intra-observer κ scores for these cut-offs (Table 1 and Table 5).
Intra-observer agreements

The mean intra-observer κ scores were 0.71, 0.60 and 0.73 for 10%, 20% and +2/+3 cut-offs respectively (Table 5). The κ score agreement for 10% and +2/+3 cut-offs is in the ‘substantial’ agreement category and for the 20% cut-off is in the ‘moderate’ agreement category. However, the κ score intra-observer agreements between all seven pathologists for the three cut-offs were not statistically different (Supplementary Figure 2).

In summary, the intra-observer agreements for the three cut-offs were reasonably good. In addition, the agreements for the three cut-offs were not statistically different from each other. Thus a good intra-observer agreement confirms the reproducibility of these cut-offs by pathologists and again this supports their use for IHC biomarkers.

The inter- and intra-observer agreements follow the same pattern i.e. ‘substantial’ agreement for 10% and +2/+3 and ‘moderate’ agreement for 20% cut-offs.
Discussion

Three IHC cut-offs, namely 10%, 20% and +2/+3 were assessed for observer agreement between pathologists. All cut-offs demonstrated good inter- and intra-observer agreement between pathologists. Similarly, all three cut-offs showed high correlation with perceived ease of scoring. Finally, the observer agreement for cytoplasmic only staining was higher than cytoplasmic/nuclear staining and cytoplasmic/membranous staining.

Establishing a cut-off for biomarker assessment is an essential pre-requisite for clinical translation. A wide range of cut-offs have been used for diagnostic, prognostic and predictive IHC biomarkers in research and clinical settings. The purpose of a cut-off for a diagnostic biomarker is to assign patients into positive or negative categories with reasonable sensitivity without compromising specificity. Based on the expression level for a candidate biomarker in cancer and normal tissue, a cut-off is established. A good diagnostic cut-off has a low probability of false positivity and false negativity. The purpose of a cut-off for a prognostic biomarker is to divide the population into categories of longer and shorter survival for the outcome. In research settings a cut-off based on percentage of positive tumour cells is mostly used. Similarly, the aim of a cut-off for predictive biomarkers is to stratify patients into likely responders and non-responders to treatment and intervention.

IHC cut-offs used for prognostic and predictive biomarkers have been investigated for observer agreement but such studies are limited for diagnostic
biomarkers. The cut-offs of 10% and 30% positive cells with strong membranous staining for HER2 have been investigated for reproducibility amongst pathologists. In addition, for oestrogen receptor (ER) and progesterone receptor (PR), the continuous H-score (range 0-300) and categorical scores (negative: H-score<1, positive: H-score ≥1) have been investigated for inter-observer agreement. These cut-offs for HER2, PR and ER are clinically important and are used in clinical practice by pathologists.

Clinically relevant cut-offs are important for biomarker evaluation. We sought to investigate three cut-offs i.e. 10%, 20% and +2/+3 with the hope that if evidence of their scoring reproducibility is provided, they could potentially help the clinical translation of IHC biomarkers. Interestingly, the purpose of cut-offs differ for different biomarkers but these three cut-offs have been used for diagnostic (S100P, pVHL, KIT, HMGI(Y), CK20, P53, Ki-67) , prognostic (Ki-67, p53) and predictive (APAF-1, EGFR) biomarkers. Therefore, investigating the strength of agreement between pathologists for these three cut-offs has significant clinical importance.

Inter-observer agreement between pathologists was used to elucidate the reliability of cut-offs. A ‘substantial’ agreement was observed with overall mean κ scores of 0.64 and 0.62 for 10% and +2/+3 cut-offs respectively, whereas ‘moderate’ agreement with a κ score of 0.59 was observed for 20% cut-off. In a study comparing the 10% positivity with 30% positivity for HER2, the mean κ scores for inter-observer agreement were 0.49 for 10% positive cells and 0.54 for 30% positive cells. Clearly, the κ scores generated for the three cut-offs under investigation in our project are comparable to the κ scores for HER2 which is
already in clinical practice as a predictive biomarker. Moreover, studies looking at the inter-observer reproducibility in histopathology and the IHC literature have shown that κ scores more than 0.60 (substantial agreement) are regarded as a good level of agreement. In comparison, κ scores less than 0.40 (fair agreement) are regarded as an unacceptably low level of agreements for diagnostic purposes.

Intra-observer agreement of the scoring and then re-scoring of the same image was used to assess reproducibility of the cut-offs. Again a pattern similar to inter-observer agreement emerged with ‘substantial’ agreements for the 10% and +2/+3 cut-offs and ‘moderate’ agreement for 20% cut-off. However, the intra-observer agreements (0.71, 0.60 and 0.73) in the present study are higher than inter-observer agreements (0.64, 0.59 and 0.62) for the three cut-offs. This finding agrees with the previous literature that the intra-observer agreement is more than the inter-observer agreement. For example the intra-observer agreement (κ=0.85) is better than the inter-observer agreement (κ=0.80) for PDX-1 IHC staining intensity in prostate cancer. In addition, the intra-observer agreement (κ=0.78) is better than the inter-observer agreement (κ=0.65) for evaluation of focal cortical dysplasia categories.

Taking 10% positive cells as a cut-off has been used for a variety of IHC biomarkers in different cancer types. These include S100P and XIAP in the differentiation of pancreatic cancer from non-neoplastic pancreatic tissue, and for a panel of napsin A, TTF 1, CK 5, and P63 in differentiating adenocarcinoma from squamous cell carcinoma of the lung. Moreover, 10% cut-off is prognostic in breast cancer for a panel of Ki67 and p53, predictive of event-free
survival in stage II colon cancer for VEGF and is predictive in rectal tumours treated with preoperative, high-dose-rate brachytherapy for APAF-1 \(^{36,38,47}\). The use of a 10% cut-off in other areas of pathology means that the more experienced pathologists in the present study will have already had experience in applying this cut-off, which is a possible explanation for why they have a higher agreement than junior pathologists. Studies have attempted to show the reproducibility of the 10% cut-off and the \(\kappa\) scores achieved in the current study (0.64, substantial agreement) is similar to the \(\kappa\) scores (0.57-0.77, moderate to substantial) in the reported literature \(^{36,48-50}\).

The 20% positive staining cut-off has also been used for a variety of IHC biomarkers. These include, Ki-67 as a prognostic biomarker in breast carcinoma \(^{51}\) and NF-E2 in the differentiation of essential thrombocythemia from primary myelofibrosis \(^{52}\). However, studies investigating the variation in interpretation of this cut-off between pathologists are very limited. The current study investigated the 20% cut-off for observer agreement and our results suggested a good level of agreement.

Moderate to strong staining intensity and any percentage of positive cells (+2/+3) as a cut-off has also been used for IHC biomarkers. These include CK20, P53, CK5/6, CD138, and Her2/Neu in the diagnosis of urothelial carcinoma in situ and the use of claudin-4 to distinguish adenocarcinoma from malignant mesothelioma in effusion cytology \(^{26,53,54}\). However, once again studies observing the variation in interpretation of this cut-off between pathologists are very limited. Our results demonstrate that this cut-off is also reliable, reproducible
and easy to score and it can be ranked second to the 10% cut-off from the current study.

The observer agreement was also assessed using staining in different cellular compartments. Staining in only the cytoplasmic compartment achieved higher agreements than other staining patterns.

The interpretation of membranous staining for HER2 in breast cancer is used in routine clinical practice. Hameed et al \(^8\) investigated inter-observer agreement using 10% positive cells with membranous staining for HER2 in breast cancer. The authors found a mean inter-observer agreement \(\kappa\) score of 0.49 \(^8\). We also investigated inter-observer agreement using 10% positive cells with membranous staining for mesothelin in pancreatic cancer and observed \(\kappa\) score agreement of 0.62. Thus 10% cut-off and membranous staining achieve reasonable observer agreement not only for HER2 in breast cancer but for other biomarker in a different cancer and warrants further investigations.

The sample size was good and seven pathologists participated in the present study. This number is comparable to the IHC biomarker and histopathology literature (4 to 7 participants) where observer agreement was investigated \(^44,55-57\). In addition, the participants in the current study were practising pathologists with variable levels of experience as compared to studies where either physicians (with no formal pathology experience) \(^44\) or researchers with experience in IHC were recruited \(^56\). Thus the results of this study provide good evidence on the use of cut-offs for IHC biomarkers.
The limitations include: the relatively few number of images due to the time constraints imposed by the clinical work of the pathologists; and all pathologists were from the same institution; the aim was to carry out the study with all of the pathologists present at one session and this was achieved for the inter-observer part but for the intra-observer part we had to arrange an extra session. An important limitation results from the fact that images were shown as a PowerPoint presentation on screen rather than using a standard microscope.

**Conclusions**

In a day-to-day clinical practice pathologists need scoring systems and cut-offs that are reproducible and easy to use\(^1\),\(^8\). A wide range of cut-offs have been used for IHC biomarkers. We selected 10%, 20% and +2/+3 cut-offs that have been utilised previously in clinical practice. These three cut-offs are reliable and reproducible achieving a reasonably good agreement level between pathologists (when compared with the literature). They could facilitate translational biomarker studies and could potentially be used by scientists who are not trained pathologists but are involved in investigating IHC biomarkers. A biomarker achieving diagnostic, prognostic and/or predictive significance with any of the three cut-offs may have translational potential. Further studies are required to assess these cut-offs with pathologists from different institutions and using a larger sample of images.
Abbreviations

IHC: Immunohistochemistry

10% cut-off: 10% positive epithelial cells

20% cut-off: 20% positive epithelial cells

+2/+3 cut-off: moderate to strong staining intensity with any proportion of positive cells

K: Kappa

ROC: Receiver operating characteristic curve

HER2: Human epidermal growth factor receptor 2

ER: Oestrogen receptor

PR: Progesterone receptor

H-score: Histoscore

CN: Cytoplasmic and/or nuclear staining

CM: Cytoplasmic and/or membranous staining

CK7: Cytokeratin 7

CK20: Cytokeratin 20

TTF1: Thyroid transcription factor 1

HMGI: High-mobility group protein I

<td>0.010</td>
</tr>
</tbody>
</table>

**Note:** *Paired sample t test

Abbreviations: C (cytoplasmic staining), CM (cytoplasmic and membranous staining) and CN (cytoplasmic and nuclear staining).
### Table 4: Multivariable linear regression for 10%, 20% and +2/+3 cut-offs as predictor variables and perceived ease of interpretation as dependent variable.

<table>
<thead>
<tr>
<th>Variables</th>
<th>Unstandardized Coefficients</th>
<th>Standardized Coefficients</th>
<th>P value</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>B</td>
<td>Std. Error</td>
<td>Beta</td>
</tr>
<tr>
<td>(Constant)</td>
<td>-5.67</td>
<td>1.07</td>
<td></td>
</tr>
<tr>
<td>10% Cut-off</td>
<td>0.71</td>
<td>0.16</td>
<td>0.41</td>
</tr>
<tr>
<td>+2/+3 Cut-off</td>
<td>0.46</td>
<td>0.12</td>
<td>0.38</td>
</tr>
<tr>
<td>20% Cut-off</td>
<td>0.51</td>
<td>0.16</td>
<td>0.34</td>
</tr>
</tbody>
</table>

**Note:** The 10%, 20% and +2/+3 are predictor variables i.e. they are variables that are predicting an outcome (the ease of interpretation). In this regression model ease of interpretation is a dependent variable i.e. a variable which “depends” on the predictor variable. The standardised beta coefficients were used as an estimate of association between predictor and dependent variable. The higher the beta coefficient the higher is the p-value significance and the stronger is the association between predictor and dependent variables. Beta coefficient in this model is highest (0.41) for 10% cut-off, followed by +2/+3 (0.38) and 20% (0.34). However, the p-value for all three cut-offs is significant showing a positive association with ease of interpretation.
Table 5: Pairwise k scores of intra-observer agreements for pathologists for the three cut-offs.

</tbody>
</table>

Note: Pairwise k scores showing intra-observer reproducibility from scoring and re-scoring (for example A-A) of all seven pathologists (A-G) in the evaluation of Immunohistochemistry using 10%, 20% and +2/+3 cut-offs.
**Figure Legends:**

**Figure 1:** Representative images of high and low inter-observer agreement between all pathologists for 10%, 20% and +2/+3 cut-offs.

**Figure 1 legend:** The high (left column grid) and low (right column grid) inter-observer agreement of IHC interpretation is shown for the three cut-offs. The staining for the three cut-offs was recorded only in the tumour epithelium. The high level agreement is attributed to the strong staining intensity and higher proportion of positive cells as illustrated in left column grid. All pathologists agreed on the images in the left column grid for all three cut-offs. However, there were differences in the number of pathologists agreeing on the images in the right column grid. For 10% cut-off (right upper image) 4/7 pathologists agreed, for 20% cut-off (right middle image) 5/7 pathologists agreed and for the +2/+3 cut-off (right lower image) 3/7 pathologists agreed.
