I. INTRODUCTION

The interference between $B_s^0$ meson decay amplitudes $J/\phi K$ directly or via mixing gives rise to a measurable $\CP$-violating phase $\phi_s$. In the Standard Model (SM), for $b \to c\bar{s}s$ transitions and ignoring subleading penguin contributions, this phase is predicted to be $-2\phi_s$, where $\phi_s = \arg(-V_{tb}V_{ts}^*/V_{td}V_{ts}^*)$ and $V_{ij}$ are elements of the Cabibbo-Kobayashi-Maskawa quark flavor mixing matrix [1].

The indirect determination via global fits to experimental data gives $2\phi_s = 0.0364 \pm 0.0016$ rad [2]. This precise indirect determination within the SM makes the measurement of $\phi_s$ interesting since new physics processes could modify the phase if new particles were to be measured. The results of performing a combined analysis with $B_s^0 \to J/\psi \pi^+ \pi^-$ decays gives $\phi_s = 0.01 \pm 0.07$ (stat) $\pm 0.01$ (syst) rad, $\Gamma_s = (0.100 \pm 0.016) \pm 0.003$ (syst) ps$^{-1}$, corresponding to the single most precise determination of $\phi_s$, $\Delta \Gamma_s$, and $\Gamma_s$. The result of performing a combined analysis with $B_s^0 \to J/\psi \pi^+ \pi^-$ decays gives $\phi_s = 0.01 \pm 0.07$ (stat) $\pm 0.01$ (syst) rad, $\Gamma_s = 0.661 \pm 0.004$ (stat) $\pm 0.006$ (syst) ps$^{-1}$, and $\Delta \Gamma_s = 0.106 \pm 0.011$ (stat) $\pm 0.007$ (syst) ps$^{-1}$. All measurements are in agreement with the Standard Model predictions.

II. PHENOMENOLOGY

The $B_s^0 \to J/\psi K^+ K^-$ decay proceeds predominantly via $B_s^0 \to J/\psi \phi$ with the $\phi$ meson subsequently decaying to $K^+ K^-$. In this case there are two intermediate vector particles, and the $K^+ K^-$ pair is in a P-wave configuration. The final state is then a superposition of $CP$-even and $CP$-odd states depending upon the relative orbital angular momentum of the $J/\psi$ and the $\phi$. The phenomenological aspects of this process are described in many articles, e.g., Refs. [13,14]. The main Feynman diagrams for $B_s^0 \to J/\psi K^+ K^-$ decays are shown in Fig. 2. The effects induced

by the subleading penguin contributions are discussed, e.g., in Ref. [15]. The same final state can also be produced with $K^+K^-$ pairs in an S-wave configuration [16]. This S-wave final state is CP-odd. The measurement of $\phi$, requires the CP-even and CP-odd components to be disentangled by analyzing the distribution of the reconstructed decay angles of the final-state particles.

In contrast to Ref. [5], this analysis uses the decay angles defined in the helicity basis, as this simplifies the angular description of the background and acceptance. The helicity angles are denoted by $\Omega = (\cos \theta_K, \cos \theta_\mu, \hat{\varphi}_h)$, and their definition is shown in Fig. 3. The polar angle $\theta_K$ ($\theta_\mu$) is the angle between the $K^+ (\mu^-)$ momentum and the direction opposite to the $B^0_s$ momentum in the $K^+K^-$ ($\mu^+\mu^-$) center-of-mass system. The azimuthal angle between the $K^+K^-$ and $\mu^+\mu^-$ decay planes is $\hat{\varphi}_h$. This angle is defined by a rotation from the $K^-$ side of the $K^+K^-$ plane to the $\mu^+$ side of the $\mu^+\mu^-$ plane. The rotation is positive in the $\mu^+\mu^-$ direction in the $B^0_s$ rest frame. A definition of the angles in terms of the particle momenta is given in the Appendix.

The decay can be decomposed into four time-dependent complex amplitudes, $A_i(t)$. Three of these arise in the P-wave decay and correspond to the relative orientation of the linear polarization vectors of the $J/\psi$ and $\phi$ mesons, where $i \in \{0, ||, \perp\}$ and refers to the longitudinal, transverse-parallel, and transverse-perpendicular orientations, respectively. The single $K^+K^-$ S-wave amplitude is denoted by $A_S(t)$.

The distribution of the decay time and angles for a $B^0_s$ meson produced at time $t = 0$ is described by a sum of ten terms, corresponding to the four polarization amplitudes and their interference terms. Each of these is given by the product of a time-dependent function and an angular function [13]:

$$\frac{d\Gamma(B^0_s \to J/\psi K^+K^-)}{d\Omega} \propto \sum_{k=1}^{10} h_k(t) f_k(\Omega).$$

(1)

The time-dependent functions $h_k(t)$ can be written as

$$h_k(t) = N_k e^{-\Gamma t} \left[ a_k \cosh(\frac{1}{2} \Delta \Gamma t) + b_k \sinh(\frac{1}{2} \Delta \Gamma t) + c_k \cos(\Delta m t) + d_k \sin(\Delta m t) \right].$$

(2)

where $\Delta m$ is the mass difference between the heavy and light $B^0_s$ mass eigenstates. The expressions for the $f_k(\Omega)$ and the coefficients of Eq. 2 are given in Table II [17,18]. The coefficients $N_k$ are expressed in terms of the $A_i(t)$ at $t = 0$, from now on denoted as $A_i$. The amplitudes are parametrized by $|A_i|e^{i\delta_i}$ with the conventions $\delta_0 = 0$ and $|A_0|^2 + |A_||^2 + |A_\perp|^2 = 1$. The S-wave fraction is defined as $F_S = |A_S|^2/(|A_0|^2 + |A_||^2 + |A_\perp|^2 + |A_S|^2) = |A_S|^2/(|A_S|^2 + 1)$.

For the coefficients $a_k, \ldots, d_k$, three CP-violating observables are introduced:

$$C = \frac{1 - |A|^2}{1 + |A|^2}, \quad S = \frac{2\Re(\lambda)}{1 + |\lambda|^2}, \quad D = \frac{2\Im(\lambda)}{1 + |\lambda|^2},$$

(3)

where the parameter $\lambda$ is defined below. These definitions for $S$ and $C$ correspond to those adopted by HFAG [19], and the sign of $D$ is chosen such that it is equivalent to the symbol $A^\text{HFAG}$ used in Ref. [19]. The CP-violating phase $\phi_s$.
is defined by $\phi_x = - \arg(\lambda)$, and hence $S$ and $D$ can be written as

$$S \equiv -\frac{2|\lambda| \sin \phi_x}{1 + |\lambda|^2}, \quad D \equiv -\frac{2|\lambda| \cos \phi_x}{1 + |\lambda|^2}.$$  \hspace{0.5cm} (4)

The parameter $\lambda$ describes $CP$ violation in the interference between mixing and decay and is derived from the $CP$-violating parameter [20] associated with each polarization state $i$,

$$\lambda_i \equiv \frac{q}{p} \frac{A_0}{A_i},$$  \hspace{0.5cm} (5)

where $A_i$ ($\tilde{A}_i$) is the amplitude for a $B^0_i$ ($\tilde{B}^0_i$) meson to decay to final state $i$ and the complex parameters $p = \langle B^0_0 | B_L \rangle$ and $q = \langle \tilde{B}^0_i | B_L \rangle$ describe the relation between mass and flavor eigenstates. The polarization states $i$ have the $CP$ eigenvalue $\eta_i = +1$ for $i \in \{0, \parallel\}$, and $\eta_i = -1$ for $i \in \{\perp, S\}$. Assuming that any possible $CP$ violation in the decay is the same for all amplitudes, then the product $\eta_i \tilde{A}_i / A_i$ is independent of $i$. The polarization-independent $CP$-violating parameter $\lambda$ is then defined such that $\lambda_i = \eta_i \lambda$. The differential decay rate for a $B^0_i$ meson produced at time $t = 0$ can be obtained by changing the sign of $c_k$ and $d_k$ and by including a relative factor $|p/q|^2$.

The expressions are invariant under the transformation

$$(\phi_x, \Delta \Gamma, \delta_0, \delta_{\parallel}, \delta_\perp, \delta_S) \rightarrow (\pi - \phi_x, -\Delta \Gamma, -\delta_0, -\delta_{\parallel}, \pi - \delta_\perp, -\delta_S),$$  \hspace{0.5cm} (6)

which gives rise to a two-fold ambiguity in the results.

</table>
In the selected $\pi^+ \pi^-$ invariant mass range, the CP-odd fraction of $B_s^0 \rightarrow J/\psi \pi^+ \pi^-$ decays is greater than 97.7% at 95% C.L. as described in Ref. [21]. As a consequence, no angular analysis of the decay products is required, and the differential decay rate can be simplified to

$$\frac{d\Gamma(B_s^0 \rightarrow J/\psi \pi^+ \pi^-)}{dt} \propto h_3(t).$$

### III. DETECTOR

The LHCb detector [22] is a single-arm forward spectrometer covering the pseudorapidity range $2 < \eta < 5$, designed for the study of particles containing $b$ or $c$ quarks. The detector includes a high-precision tracking system consisting of a silicon-strip vertex detector surrounding the $pp$ interaction region, a large-area silicon-strip detector located upstream of a dipole magnet with a bending power of about 4 Tm, and three stations of silicon-strip detectors and straw drift tubes placed downstream. The combined tracking system has momentum resolution $\Delta p/p$ that varies from 0.4% at 5 GeV/$c$ to 0.6% at 100 GeV/$c$ and an impact parameter resolution of 20 $\mu$m for tracks with high transverse momentum. Charged hadrons are identified using two ring-imaging Cherenkov detectors [23]. Photon, electron, and hadron candidates are identified by a calorimeter system consisting of scintillating-pad and preshower detectors, an electromagnetic calorimeter, and a hadron calorimeter. Muons are identified by a system composed of alternating layers of iron and multiwire proportional chambers. The trigger consists of a hardware stage, based on information from the calorimeter and muon systems, followed by a software stage that applies a full event reconstruction [24].

Simulated $pp$ collisions are generated using PYTHIA 6.4 [25] with a specific LHCb configuration [26]. Decays of hadronic particles are described byEvtGen [27], in which final-state radiation is generated using PHOTOS [28]. The interaction of the generated particles with the detector and its response are implemented using the GEANT4 toolkit [29] as described in Ref. [30].

### IV. SELECTION OF $B_s^0 \rightarrow J/\psi K^+ K^-$ CANDIDATES

The reconstruction of $B_s^0 \rightarrow J/\psi K^+ K^-$ candidates proceeds using the decays $J/\psi \rightarrow \mu^+ \mu^-$ combined with a pair of oppositely-charged kaons. Events are first required to pass a hardware trigger [24], which selects events containing muon or hadron candidates with a high transverse momentum ($p_T$). The subsequent software trigger [24] is composed of two stages, the first of which performs a partial event reconstruction. Two types of first-stage software triggers are employed. For the first type, events are required to have two well-identified oppositely-charged muons with invariant mass larger than 2.7 GeV/$c^2$. This trigger has an almost uniform acceptance as a function of decay time and will be referred to as unbiased. For the second type, there must be at least one muon (one high-$p_T$ track) with a transverse momentum larger than 1 GeV/$c$ (1.7 GeV/$c$) and an impact parameter larger than 100 $\mu$m with respect to the primary vertex (PV). This trigger introduces a nontrivial acceptance as a function of decay time and will be referred to as biased. The second stage of the trigger performs a full event reconstruction and only retains events containing a $\mu^+ \mu^-$ pair with invariant mass within 120 MeV/$c^2$ of the $J/\psi$ mass [11] and that form a vertex that is significantly displaced from the PV, introducing another small decay-time biasing effect.

The final $B_s^0$ candidate selection is performed by applying kinematic and particle identification criteria to the final-state tracks. The $J/\psi$ meson candidates are formed from two oppositely-charged particles, originating from a common vertex, which have been identified as muons and which have $p_T$ larger than 500 MeV/$c$. The invariant mass of the $\mu^+ \mu^-$ pair, $m(\mu^+ \mu^-)$, must be in the range [3030, 3150] MeV/$c^2$. During subsequent steps of the selection, $m(\mu^+ \mu^-)$ is constrained to the $J/\psi$ mass [11].

The $K^+ K^-$ candidates are formed from two oppositely-charged particles that have been identified as kaons and that originate from a common vertex. The $K^+ K^-$ pair is required to have a $p_T$ larger than 1 GeV/$c$. The invariant mass of the $K^+ K^-$ pair, $m(K^+ K^-)$, must be in the range [990, 1050] MeV/$c^2$.

The $B_s^0$ candidates are reconstructed by combining the $J/\psi$ candidate with the $K^+ K^-$ pair, requiring their invariant mass $m(J/\psi K^+ K^-)$ to be in the range [5200, 5550] MeV/$c^2$. The decay time, $t$, of the $B_s^0$ candidate is calculated from a vertex and kinematic fit that constrains the $B_s^0 \rightarrow J/\psi K^+ K^-$ candidate to originate from its associated PV [31]. The $\chi^2$ of the fit (which has 7 degrees of freedom) is required to be less than 35. Multiple $B_s^0$ candidates are found in less than 1% of events; in these cases the candidate with the smallest $\chi^2$ is chosen. $B_s^0$ candidates are required to have decay time in the range [0.3, 14.0] ps; the lower bound on the decay time suppresses a large fraction of the prompt combinatorial background while having a negligible effect on the sensitivity to $\phi_s$. The kinematic fit evaluates an estimated decay-time uncertainty, $\sigma_t$. Candidates with $\sigma_t$ larger than 0.12 ps are removed from the event sample.

Figure 4 shows the $m(J/\psi K^+ K^-)$ distribution for events originating from both the unbiased and biased triggers, along with corresponding projection of an unbinned maximum log-likelihood fit to the sample. The probability density function (PDF) used for the fit is composed of the sum of two Gaussian functions with a common mean and separate widths and an exponential function for the combinatorial background. In total, after the trigger and full offline selection requirements, there are $27,617 \pm 115$ $B_s^0 \rightarrow J/\psi K^+ K^-$ signal events found by the fit. Of these, 23,502 $\pm 107$ were selected by the unbiased trigger, and
The uncertainties quoted here come from propagating the systematic uncertainty on the signal fraction evaluated by the fit. The background has been subtracted using the sPlot technique with \( \text{sPlot} \) [32]. The scale factors are estimated from a sample of prompt \( \mu^+ \mu^- K^+ K^- \) candidates that pass the same selection criteria as the signal except for those that affect the decay-time distribution. This sample consists primarily of prompt combinations that have a true decay time of zero. Consequently, the shape of the decay-time distribution close to zero is representative of the resolution function itself.

Prompt combinations for which the muon pair originates from a real \( J/\psi \) meson have a better resolution than those with random muon pairs. Furthermore, fully simulated events confirm that the resolution evaluated using prompt \( J/\psi \rightarrow \mu^+ \mu^- \) decays with two random kaons is more representative for the resolution of \( B_s^0 \) signal decays than the purely combinatorial background. Consequently, in the data only \( J/\psi K^+ K^- \) events are used to estimate the resolution function. These are isolated using the sPlot method to subtract the \( \mu^+ \mu^- \) combinatorial background.

The background-subtracted decay-time distribution for \( J/\psi K^+ K^- \) candidates is shown in Fig. 7 using linear and logarithmic scales. The distribution is characterized by a prompt peak and a tail due to \( J/\psi \) mesons from \( B \) decays.

\[
R(t; \sigma_i) = \sum_{i=1}^{3} \frac{f_i}{\sqrt{2\pi r_i \sigma_i}} \exp \left[ -\frac{(t - d)^2}{2r_i^2 \sigma_i^2} \right],
\]

where \( d \) is a common small offset of a few fs, \( r_i \) are event-independent resolution scale factors, and \( f_i \) is the fraction of each Gaussian component, normalized such that \( \sum f_i = 1 \).

4115 ± 43 were exclusively selected by the biased trigger. The uncertainties quoted here come from propagating the uncertainty on the signal fraction evaluated by the fit. The background has been subtracted using the sPlot technique with \( \text{sPlot} \) [32]. Curves for the fitted contributions from signal (dotted red), background (dotted green), and their combination (solid blue) are overlaid.

V. DECAY-TIME RESOLUTION

If the decay-time resolution is not negligibly small compared to the \( B_s^0 \)-meson oscillation period \( 2\pi/\Delta m_s \approx 350 \) fs, it affects the measurement of the oscillation amplitude, and thereby \( \phi_s \). For a given decay-time resolution, \( \sigma_r \), the dilution of the amplitude can be expressed as \( D = \exp(-\sigma_r^2 \Delta m_s^2/2) \) [34]. The relative systematic uncertainty on the dilution directly translates into a relative systematic uncertainty on \( \phi_s \).

For each reconstructed candidate, \( \sigma_j \) is estimated by the vertex fit with which the decay time is calculated. The signal distribution of \( \sigma_j \) is shown in Fig. 6, where the sPlot technique is used to subtract the background. To account for the fact that track parameter resolutions are not perfectly calibrated and that the resolution function is not Gaussian, a triple Gaussian resolution model is constructed:

\[
R(t; \sigma_j) = \sum_{i=1}^{3} \frac{f_i}{\sqrt{2\pi r_i \sigma_i}} \exp \left[ -\frac{(t - d)^2}{2r_i^2 \sigma_i^2} \right],
\]

where \( d \) is a common small offset of a few fs, \( r_i \) are event-independent resolution scale factors, and \( f_i \) is the fraction of each Gaussian component, normalized such that \( \sum f_i = 1 \).
The resolution model parameters are determined by fitting the distribution with a decay-time model that consists of a prompt peak and two exponential functions, convolved with the resolution model given in Eq. 8.

The per-event resolution receives contributions both from the vertex resolution and from the momentum resolution. The latter contribution is proportional to the decay time and cannot be calibrated with the prompt resolution. The vertex contribution and the momentum contribution have a common scale. This assumption is tested in simulations, and a systematic uncertainty directly translates to a decrease in the reconstruction efficiency for tracks with a large impact parameter with respect to the beam line. This effect is present both in the trigger and the offline reconstruction and translates to a decrease in the $B_s^0$-meson reconstruction efficiency as a function of its decay time. This decrease is parametrized by a linear acceptance function $\varepsilon(t) \approx (1 + \beta t)$, which multiplies the time-dependent PDF described below. The parametrization is determined using a control sample of $B^\pm \rightarrow J/\psi K^\pm$ events from data and simulated $B_s^0 \rightarrow J/\psi \phi$ events, leading to $\beta = (-8.3 \pm 4.0) \times 10^{-3}$ ps$^{-1}$. The uncertainty directly translates to a $4.0 \times 10^{-3}$ ps$^{-1}$ systematic uncertainty on $\Gamma_s$.

Secondly, a nontrivial decay-time acceptance is introduced by the trigger selection. Binned functional descriptions of the acceptance for the unbiased and biased triggers are obtained from the data by exploiting the sample of $B_s^0$ candidates that

VI. ACCEPTANCE

There are two distinct decay-time acceptance effects that influence the $B_s^0$ decay-time distribution. First, there is a decrease in reconstruction efficiency for tracks with a large impact parameter with respect to the beam line. This effect is present both in the trigger and the offline reconstruction and translates to a decrease in the $B_s^0$-meson reconstruction efficiency as a function of its decay time. This decrease is parametrized by a linear acceptance function $\varepsilon(t) \approx (1 + \beta t)$, which multiplies the time-dependent $B_s^0 \rightarrow J/\psi K^+ K^-$ PDF described below. The parametrization is determined using a control sample of $B^\pm \rightarrow J/\psi K^\pm$ events from data and simulated $B_s^0 \rightarrow J/\psi \phi$ events, leading to $\beta = (-8.3 \pm 4.0) \times 10^{-3}$ ps$^{-1}$. The uncertainty directly translates to a $4.0 \times 10^{-3}$ ps$^{-1}$ systematic uncertainty on $\Gamma_s$.

Secondly, a nontrivial decay-time acceptance is introduced by the trigger selection. Binned functional descriptions of the acceptance for the unbiased and biased triggers are obtained from the data by exploiting the sample of $B_s^0$ candidates that

model is $0.72 \pm 0.02$. This dilution corresponds to an effective single Gaussian resolution of approximately 45 fs. The systematic uncertainty accounts for uncertainties due to the momentum resolution scale and other differences between the control sample and signal decays. It is derived from simulations.

The sample used to extract the physics parameters of interest consists only of events with $t > 0.3$ ps. The observed decay-time distribution of these events is not sensitive to details of the resolution function. Therefore, in order to simplify the fit procedure, the resolution function for the final fit (described in Sec. VIII) is modelled with a single Gaussian distribution with a resolution scale factor, $r_t$, chosen such that its effective dilution corresponds to that of the multiple Gaussian model. This scale factor is $r_t = 1.45 \pm 0.06$. 

FIG. 7 (color online). Decay-time distribution of prompt $J/\psi K^+ K^-$ candidates. The curve (solid blue) is the decay-time model convolved with a Gaussian resolution model. The decay-time model consists of a delta function for the prompt component and two exponential functions with different decay constants, which represent the $B_s^0 \rightarrow J/\psi K^+ K^-$ signal and long-lived background, respectively. The decay constants are determined from the fit. The same data set is shown in both plots, on different scales.
are also selected by a trigger that has no decay-time bias but was only used for a fraction of the recorded data. Figure 8 shows the corresponding acceptance functions that are included in the fit described in Sec. VIII.

The acceptance as a function of the decay angles is not uniform due to the forward geometry of LHCb and the requirements placed upon the momenta of the final-state particles. The three-dimensional acceptance function, $e_\Omega$, is determined using simulated events that are subjected to the same trigger and selection criteria as the data. Figure 9 shows the angular efficiency as a function of each decay angle, integrated over the other two angles. The relative acceptances vary by up to 20% peak to peak. The dominant effect in $\cos \theta_\mu$ is due to the $p_T$ cuts applied to the muons.

The acceptance is included in the unbinned maximum likelihood fitting procedure to signal weighted distributions (described in Sec. VIII). Since only a PDF to describe the signal is required, the acceptance function needs to be included only in the normalization of the PDF through the ten integrals $\int d\Omega e_\Omega(\Omega)f_\Omega(\Omega)$. The acceptance factors for each event $i$, $e_\Omega(\Omega_i)$, appear only as a constant sum of logarithms and may be ignored in the likelihood maximization. The ten integrals are determined from the fully simulated events using the procedure described in Ref. [35].

VII. TAGGING THE $B_s^0$ FLAVOR AT PRODUCTION

Each reconstructed candidate is identified by flavor-tagging algorithms as either a $B_s^0$ meson ($q = +1$) or a $\bar{B}_s^0$ meson ($q = -1$) at production. If the algorithms are unable to make a decision, the candidate is untagged ($q = 0$).

The tagging decision, $q$, is based upon both opposite-side and same-side tagging algorithms. The opposite-side (OS) tagger relies on the pair production of $b$ and $\bar{b}$ quarks and infers the flavor of the signal $B_s^0$ meson from the identification of the flavor of the other $b$ hadron. The OS tagger uses the charge of the lepton ($\mu, e$) from semileptonic $b$ decays, the charge of the kaon from the $b \rightarrow c \rightarrow s$ decay chain, and the charge of the inclusive secondary vertex reconstructed from $b$-hadron decay products. The same-side kaon (SSK) tagger exploits the hadronization process of the $b$ (or $\bar{b}$) quark forming the signal $B_s^0 (\bar{B}_s^0)$ meson. In events with a $B_s^0$ candidate, the fragmentation of a $b$ quark can lead to an extra $s$ quark being available to form a hadron, often leading to a charged kaon. This kaon is correlated to the signal $B_s^0$ in phase space, and the sign of the charge identifies its initial flavor.

The probability that the tagging determination is wrong (estimated wrong-tag probability, $\eta$) is based upon the output
FIG. 10 (color online). Average measured wrong-tag probability (ω) vs estimated wrong-tag probability (η) calibrated on $B^+ \rightarrow J/ \psi K^+$ signal events for the OS tagging combinations for the background-subtracted events in the signal mass window. Points with errors are data, and the red curve represents the result of the wrong-tag probability calibration, corresponding to the parameters of Table III.

of a neural network trained on simulated events. It is subsequently calibrated with data in order to relate it to the true wrong-tag probability of the event, ω, as described below.

The tagging decision and estimated wrong-tag probability are used event by event in order to maximize the tagging power, $e_{\text{tag}} D^2$, which represents the effective reduction of the signal sample size due to imperfect tagging. In this expression $e_{\text{tag}}$ is the tagging efficiency, i.e., the fraction of events that are assigned a nonzero value of $q$, and $D = 1 - 2 \omega$ is the dilution.

A. Opposite-side tagging

The OS tagging algorithms and the procedure used to optimize and calibrate them are described in Ref. [36]. In this paper the same approach is used, updated to use the full 2011 data set.

Calibration of the estimated wrong-tag probability, η, is performed using approximately 250,000 $B^+ \rightarrow J/ \psi K^+$ events selected from data. The values of $q$ and η measured by the OS taggers are compared to the known flavor, which is determined by the charge of the final-state kaon. Figure 10 shows the average wrong-tag probability in the $B^- \rightarrow J/ \psi K^-$ control channel in bins of η. For calibration purposes a linear relation is assumed;

$$\omega(\eta) = p_0 + \frac{\Delta p_0}{2} + p_1(\eta - \langle \eta \rangle),$$

$$\bar{\omega}(\eta) = p_0 - \frac{\Delta p_0}{2} + p_1(\eta - \langle \eta \rangle),$$

where $\omega(\eta)$ and $\bar{\omega}(\eta)$ are the calibrated probabilities for a wrong-tag assignment for $B$ and $\bar{B}$ mesons, respectively. This parametrization is chosen to minimize the correlation between the parameters $p_0$ and $p_1$. The resulting values of the calibration parameters $p_0$, $p_1$, $\Delta p_0$, and $\langle \eta \rangle$ (the mean value of η in the sample) are given in Table III. The systematic uncertainties for $p_0$ and $p_1$ are determined by comparing the tagging performance for different decay channels, comparing different data-taking periods, and modifying the assumptions of the fit model. The asymmetry parameter $\Delta p_0$ is obtained by performing the calibration separately for $B^+$ and $B^-$ decays. No significant difference of the tagging efficiency or of $p_1$ measured ($\Delta e_{\text{tag}} = (0.00 \pm 0.10)\%$, $\Delta p_1 = 0.06 \pm 0.04$). Figure 10 shows the relation between $\omega$ and η for the full data sample.

The overall effective OS tagging power for $B^0_s \rightarrow J/ \psi K^+ K^-$ candidates is $e_{\text{tag}} D^2 = (2.29 \pm 0.06)\%$, with an efficiency of $e_{\text{tag}} = (33.00 \pm 0.28)\%$ and an effective average wrong-tag probability of $(36.83 \pm 0.15)\%$ (statistical uncertainties only).

B. Same-side kaon tagging

One of the improvements introduced in this analysis compared to Ref. [5] is the use of the SSK tagger. The SSK tagging algorithm was developed using large samples of simulated $B^0_s$ decays to $D_s^- \pi^+$ and $J/ \psi \phi$ and is documented in Ref. [37]. The algorithm preferentially selects kaons originating from the fragmentation of the signal $B^0_s$ meson and rejects particles that originate either from the opposite-side $B$ decay or the underlying event. For the optimization, approximately 26,000 $B^0_s \rightarrow D_s^- \pi^+$ data events are used. The same fit procedure employed to determine the $B^0_s$ mixing frequency $\Delta m_s$ [38] is used to maximize the effective tagging power $e_{\text{tag}} D^2$.

The calibration was also performed using $B^0_s \rightarrow D_s^- \pi^+$ events and assuming the same linear relation given by Eq. 10. The resulting values of the calibration parameters $(p_0, p_1, \Delta p_0)$ are given in the second row of Table III. In contrast to the OS tagging case, it is more challenging to measure $p_0$ and $p_1$ separately for true $B$ or $\bar{B}$ mesons at production using $B^0_s \rightarrow D_s^- \pi^+$ events. Therefore, assuming that any tagging asymmetry is caused by the difference

<table>

in interaction with matter of \( K^+ \) and \( K^- \), \( \Delta p_0 \) is estimated using \( B^+ \rightarrow J/\psi K^- \), where the \( p \) and \( p_1 \) distributions of the OS tagged kaons are first reweighted to match those of SSK tagged kaons from a large sample of fully simulated \( B_s \rightarrow D_s^- \pi^+ \) events.

The effective SSK tagging power for \( B_s \rightarrow J/\psi K^+ K^- \) events is \( \varepsilon_{\text{tag}}^D = (0.89 \pm 0.17)\% \), and the tagging efficiency is \( \varepsilon_{\text{tag}} = (10.26 \pm 0.18)\% \) (statistical uncertainties only).

### C. Combination of OS and SSK tagging

Only a small fraction of tagged events are tagged by both the OS and the SSK algorithms. The algorithms are uncorrelated as they select mutually exclusive charged particles, either in terms of the impact parameter significance with respect to the PV or in terms of the particle identification requirements. The two tagging results are combined taking into account both decisions and their corresponding estimate of \( \eta \). The combined estimated wrong-tag probability and the corresponding uncertainties are obtained by combining the individual calibrations for the OS and SSK tagging and propagating their uncertainties according to the procedure defined in Ref. [36]. To simplify the fit implementation, the statistical and systematic uncertainties on the combined wrong-tag probability are assumed to be the same for all of these events. They are defined by the average values of the corresponding distributions computed event by event. The effective tagging power for these OS + SSK tagged events is \( \varepsilon_{\text{tag}}^D = (0.51 \pm 0.03)\% \), and the tagging efficiency is \( \varepsilon_{\text{tag}} = (3.90 \pm 0.11)\% \).

### D. Overall tagging performance

The overall effective tagging power obtained by combining all three categories is \( \varepsilon_{\text{tag}}^D = (3.13 \pm 0.12 \pm 0.20)\% \), the tagging efficiency is \( \varepsilon_{\text{tag}} = (39.36 \pm 0.32)\% \), and the wrong-tag probability is \( \omega = 35.9\% \). Figure 11 shows the distributions of the estimated wrong-tag probability \( \eta \) of the \( B_s \rightarrow J/\psi K^+ K^- \) signal events obtained with the sPlot technique using \( m(J/\psi K^+ K^-) \) as the discriminating variable.

### VIII. MAXIMUM-LIKELIHOOD FIT PROCEDURE

Each event is given a signal weight, \( W_s \), using the sPlot [32] method with \( m(J/\psi K^+ K^-) \) as the discriminating variable. A weighted fit is then performed using a signal-only PDF, denoted by \( S \), the details of which are described below. The joint negative log likelihood, \( L \), constructed as

\[
-\ln L = -\alpha \sum_{\text{events } i} W_i \ln S_i
\]

is minimized in the fit, where the factor \( \alpha = \sum W_i / \sum W_i^2 \) is used to include the effect of the weights in the determination of the uncertainties [39].

#### A. Mass model used for weighting

The signal mass distribution, \( S_m(m(J/\psi K^+ K^-)) \), is modelled by a double Gaussian function. The free parameters in the fit are the common mean, \( m_{B^0} \); the width of the narrower Gaussian function, \( \sigma_m \); the ratio of the second to the first Gaussian width, \( r_{21} \); and the fraction of the first Gaussian, \( f_1 \).

The background mass distribution, \( B_m(m(J/\psi K^+ K^-)) \), is modelled by an exponential function. The full PDF is then constructed as

\[
P_m = f_s S_m + (1 - f_s) B_m
\]

where \( f_s \) is the signal fraction. Figure 4 shows the result of fitting this model to the selected candidates.

#### B. Dividing the data into bins of \( m(K^+ K^-) \)

The events selected for this analysis are within the \( m(K^+ K^-) \) range \( [990, 1050] \) MeV/c\(^2\). The data are divided into six independent sets, where the boundaries are given in Table IV. Binning the data this way leads to an improvement...
in statistical precision by separating events with different signal fractions, and the analysis becomes insensitive to correction factors, which must be applied to each of the three S-wave interference terms in the differential decay rate \((f_s, f_o, f_{i0})\) in Table II). These terms are required to account for an averaging effect resulting from the variation within each bin of the S-wave line shape (assumed to be approximately uniform) relative to that of the P-wave (a relativistic Breit-Wigner function). In each bin, the correction factors are calculated by integrating the product of \(p\) with \(s^*\), which appears in the interference terms between the P- and S-wave, where \(p\) and \(s\) are the normalized \(m(K^+K^-)\) line shapes and \(*\) is the complex conjugation operator,

\[
\int_{m^L}^{m^R} ps^* dm(K^+K^-) = C_{SP}e^{-i\theta_{SP}},
\]

where \([m^L, m^R]\) denotes the boundaries of the \((m(K^+K^-))\) bin, \(C_{SP}\) is the correction factor, and \(\theta_{SP}\) is absorbed in the measurements of \(\delta_S - \delta_{1/2}\). The \(C_{SP}\) correction factors are given in Table IV. By using several bins, these factors are close to one, whereas if only a single bin was used, the correction would differ substantially from one. The effect of these factors on the fit results is very small and is discussed further in Sec. X, where a different S-wave line shape is considered. Binning the data in \((m(K^+K^-))\) allows a repetition of the procedure described in Ref. [40] to resolve the ambiguous solution described in Sec. I by inspecting the trend in the phase difference between the S- and P-wave components.

The weights, \(W_i\), are determined by performing a simultaneous fit to the \((m(J/\psi K^+K^-))\) distribution in each of the \((m(K^+K^-))\) bins, using a common set of signal mass parameters and six independent background mass parameters. This fit is performed for \((m(J/\psi K^+K^-))\) in the range \([5200, 5550]\) MeV/c\(^2\), and the results for the signal mass parameters are shown in Table V.

### C. Signal PDF

The physics parameters of interest in this analysis are \(\Gamma_j, \Delta \Gamma_j, |A_0|^2, |A_{1/2}|^2, F_S, \delta_||, \delta_{1/2}, \delta_S, \phi_s, |\lambda|\) and \(\Delta m_s\), all of which are defined in Sec. II. The signal PDF, \(S\), is a function of the decay time, \(t\), and angles, \(\Omega\), and is conditional upon the estimated wrong-tag probability for the event, \(\eta\), and the estimate of the decay-time resolution for the event, \(\sigma_t\). The data are separated into disjoint sets corresponding to each of the possible tagging decisions \(q \in \{-1, 0, +1\}\) and the unbiased and biased trigger samples. A separate signal PDF, \(S_q(t, \Omega|\sigma_t, \eta; Z, N)\), is constructed for each event set, where \(Z\) represents the physics parameters and \(N\) represents nuisance parameters described above.

The \(S_q\) are constructed from the differential decay rates of \(B^0_s\) and \(\bar{B}^0_s\) mesons described in Sec. II. Denoting \(d^4\Gamma(B^0_s \to J/\psi K K)/d\Omega f\) by \(X\) and \(d^4\Gamma(\bar{B}^0_s \to J/\psi K K)/d\Omega f\) by \(\bar{X}\), then

\[
S_q = \frac{s_q}{\int s_q d\Omega f},
\]

where

\[
\begin{align*}
    s_{+1} &= \left\{[(1 - \omega)X(t, \Omega; Z) + \bar{\omega}\bar{X}(t, \Omega; Z)] \right. \\
    &\left. \otimes R(t; \sigma_I) e_i(t) e_\Omega(\Omega) \right\}, \\
    s_{-1} &= \left\{[\omega X(t, \Omega; Z) + (1 - \bar{\omega})\bar{X}(t, \Omega; Z)] \right. \\
    &\left. \otimes R(t; \sigma_I) e_i(t) e_\Omega(\Omega) \right\}, \\
    s_0 &= \frac{1}{2} \left\{[X(t, \Omega; Z) + \bar{X}(t, \Omega; Z)] \otimes R(t; \sigma_I) e_i(t) e_\Omega(\Omega) \right\}.
\end{align*}
\]

### Asymmetries in the tagging efficiencies and relative magnitudes of the production rates for \(B^0_s\) and \(\bar{B}^0_s\) mesons, as well as the factor \(|p/q|^2\), are not included in the model. Sensitivity to these effects is reduced by the use of separately normalized PDFs for each of the tagging decisions, and any residual effect is shown to be negligible.

All physics parameters are free in the fit apart from \(\Delta m_s\), which is constrained to the value measured by LHCb of \(17.63 \pm 0.11\) ps\(^{-1}\) [38]. The parameter \(\delta_S - \delta_{1/2}\) is used in the minimization instead of \(\delta_S\) as there is a large (90%) correlation between \(\delta_S\) and \(\delta_{1/2}\).

In these expressions the terms \(\omega\) and \(\bar{\omega}\) represent the wrong-tag probabilities for a candidate produced as a genuine \(B^0_s\) or \(\bar{B}^0_s\) meson, respectively, and are a function of \(\eta\) and the (nuisance) calibration parameters \((p_1, p_0, \langle \eta \rangle, \Delta p_0)\) as given in Eq. 10. The calibration parameters are given in Table III and are all included in

### TABLE IV. Bins of \((m(K^+K^-))\) used in the analysis and the \(C_{SP}\) correction factors for the S-wave interference term, assuming a uniform distribution of nonresonant \(K^+K^-\) contribution and a nonrelativistic Breit-Wigner shape for the decays via the \(\phi\) resonance.

the fit via Gaussian constraints with widths equal to their uncertainties.

The expressions are convolved with the decay-time resolution function, \( R(t; \sigma_t) \) (Sec. V). The scale factor parameter, \( r_s \), is included in the fit with its value constrained by a Gaussian constraint with width equal to its uncertainty. The \( e_{i}(t) \) and \( e_{i\Omega}(\Omega) \) terms are the decay-time acceptance and decay-angle acceptance, respectively. The two different trigger samples have different decay-time acceptance functions. These are described in Sec. VI.

Since this weighted fit uses only a signal PDF, there is no need to include the distributions of either the estimated wrong-tag probability, \( \epsilon_t \), or the decay-time resolution for each event, \( \sigma_t \). The physics parameter estimation is then performed by a simultaneous fit to the weighted data in each of the \( m(K^+ K^-) \) bins for each of the two trigger samples. All parameters are common, except for the S-wave fraction \( F_s \) and the phase difference \( \delta_S - \delta_L \), which are independent parameters for each range.

**IX. RESULTS FOR \( B^0_s \rightarrow J/\psi K^+ K^- \) DECAYS**

The results of the fit for the principal physics parameters are given in Table VI for the solution with \( \Delta \Gamma_s > 0 \), showing both the statistical and the total systematic uncertainties described in Sec. X.

The statistical correlation matrix is shown in Table VII. The projections of the decay-time and angular distributions are shown in Fig. 12. It was verified that the observed uncertainties are compatible with the expected sensitivities by generating and fitting to a large number of simulated experiments.

Figure 13 shows the 68\%, 90\%, and 95\% C.L. contours obtained from the two-dimensional profile likelihood ratio in the \( (\Delta \Gamma_s, \phi_s) \) plane, corresponding to decreases in the log-likelihood of 1.15, 2.30, and 3.00, respectively. Only statistical uncertainties are included. The SM expectation [41] is shown.

The results for the S-wave parameters are shown in Table VIII. The likelihood profiles for these parameters are nonparabolic and are asymmetric. Therefore, the 68\% C.L. intervals obtained from the likelihood profiles, corresponding to a decrease of 0.5 in the log-likelihood, are reported. The variation of \( \delta_S - \delta_L \) with \( m(K^+ K^-) \) is shown in Fig. 14. The decreasing trend confirms that expected for the physical solution with \( \phi_s \) close to zero, as found in Ref. [40].

All results have been checked by splitting the data set into subsamples to compare different data-taking periods, magnet polarities, \( B^0_s \) tags, and trigger categories. In all cases the results are consistent between the independent subsamples. The measurements of \( \phi_c, \Delta \Gamma_s, \) and \( \Gamma_s \) are the most precise to date. Both \( \Delta \Gamma_s \) and \( \phi_s \) agree well with the SM expectation [2,41].

These data also allow an independent measurement of \( \Delta m_s \) without constraining it to the value reported in Ref. [38]. This is possible because there are several terms in the differential decay rate of Eq. 1, principally \( h_4 \) and \( h_6 \), which contain sinusoidal terms in \( \Delta m_s t \) that are not multiplied by \( \sin \phi_s \). Figure 15 shows the likelihood profile as a function of \( \Delta m_s \) from a fit to the data where \( \Delta m_s \) is not constrained. The result of the fit gives

\[
\Delta m_s = 17.70 \pm 0.10(\text{stat}) \pm 0.01(\text{syst}) \text{ ps}^{-1},
\]

which is consistent with other measurements [38,42–44].

**X. SYSTEMATIC UNCERTAINTIES FOR \( B^0_s \rightarrow J/\psi K^+ K^- \) DECAYS**

The parameters, \( \Delta m_s \); the tagging calibration parameters; and the event-by-event proper time scaling factor, \( r_t \), are all allowed to vary within their uncertainties in the fit.
Therefore, the systematic uncertainties from these sources are included in the statistical uncertainty on the physics parameters. The remaining systematic effects are discussed below and summarized in Tables IX, X, and XI.

The parameters of the $m(J/\psi K^+K^-)/C_0$ fit model are varied within their uncertainties, and a new set of event weights are calculated. Repeating the full decay time and angular fit using the new weights gives negligible differences with respect to the results of the nominal fit. The assumption that $m(J/\psi K^+K^-)$ is independent of the decay-time and angle variables is tested by reevaluating the weights in bins of the decay time and angles. Repeating the full fit with the modified weights gives new estimates of the physics parameter values in each bin. The total systematic uncertainty is computed from the square root of the sum of the individual variances, weighted by the number of signal events in each bin in cases where a significant difference is observed.

Using simulated events, the only identified peaking background is from $B_0^0 \rightarrow J/\psi K^*(892)^0$ events where the pion from the $K^*(892)^0$ decay is misidentified as a kaon. The fraction of this contribution was estimated from the simulation to be at most 1.5% for $m(J/\psi K^+K^-)$ in the range $[5200, 5550]$ MeV/$c^2$. The effect of this background (which is not included in the PDF modelling) was estimated by embedding the simulated $B_0^0 \rightarrow J/\psi K^*(892)^0$ events in the signal sample and repeating the fit. The resulting variations are taken as systematic uncertainties. The contribution of $B_0^0$ mesons coming from the decay of $B_0^0$ mesons is estimated to be negligible.

Since the angular acceptance function, $e_\phi$, is determined from simulated events, it is important that the

</table>

A systematic uncertainty is determined by repeating the fits with the bin values varied randomly within their statistical precision. The standard deviation of the distribution of central values obtained for each fit parameter is then assigned as the systematic uncertainty. The slope of the acceptance correction at large lifetimes is $\beta = (-8.3 \pm 4.0) \times 10^{-3}$ ps$^{-1}$. This leads to a $4.0 \times 10^{-3}$ ps$^{-1}$ systematic uncertainty on $\Gamma_s$.

The uncertainty on the LHCb length scale is estimated to be at most 0.020%, which translates directly in an uncertainty on $\Gamma_s$ and $\Delta \Gamma_s$ of 0.020% with other parameters being unaffected. The momentum scale uncertainty is at most 0.022%. As it affects both the reconstructed momentum and mass of the $B^0_s$ meson, it cancels to a large extent, and the resulting effect on $\Gamma_s$ and $\Delta \Gamma_s$ is negligible.

The $C_{SB}$ factors (Table IV) used in the nominal fit assume a nonresonant shape for the S-wave contribution. As a cross-check, the factors are reevaluated assuming a Flatté shape [45], and the fit is repeated. There is a negligible effect on all physics parameters except $\delta_S - \delta_+$. A small shift (approximately 10% of the statistical uncertainty) is observed in $\Gamma_s$.

uncertainty) is observed in $\delta_S - \delta_L$ in each bin of $m(K^+K^-)$ and is assigned as a systematic uncertainty.

A possible bias of the fitting procedure is investigated by generating and fitting many simplified simulated experiments of equivalent size to the data sample. The resulting biases are small, and those that are not compatible with zero within three standard deviations are quoted as systematic uncertainties.

The small offset, $d$, in the decay-time resolution model was set to zero during the fitting procedure. A corresponding systematic uncertainty was evaluated using simulated experiments and found to be negligible for all parameters apart from $\phi_d$ and $\delta_L$.

A measurement of the asymmetry that results from $CP$ violation in the interference between $B^0_d$-$\bar{B}^0_d$ mixing and decay is potentially affected by $CP$ violation in the mixing, direct $CP$ violation in the decay, production asymmetry, and tagging asymmetry. In the previous analysis [5], an explicit systematic uncertainty was included to account for this. In this analysis the fit parameter $|\lambda|$ is added, separate
tagging calibrations are used for $B^0_s$ and $B^0$ decisions, as well as separate normalizations of the PDF for each tagging decision. Any residual effects due to tagging efficiency asymmetry and production asymmetry are shown to be negligible through simulation studies.

The measurement of $\Delta m_s$ determined from these data alone without applying a constraint has been reported in Sec. IX. The dominant sources of systematic uncertainty come from the knowledge of the LHCb length and momentum scales. No significant systemetic effect is observed after varying the decay-time and angular acceptances and the decay-time resolution. Adding all contributions in quadrature gives a total systematic uncertainty of $\pm 0.01$ ps$^{-1}$.

XI. RESULTS FOR $B^0_s \to J/\psi \pi^+ \pi^-$ DECAYS

The $B^0_s \to J/\psi \pi^+ \pi^-$ analysis used in this paper is unchanged with respect to Ref. [6] except for:

1. the inclusion of the same-side kaon tagger in the same manner as has already been described for the $B^0_s \to J/\psi K^+ K^-$ sample. This increases the number of tagged signal candidates to 2146 OS-only, 497 SSK-only, and 293 overlapped events compared to 2445 in Ref. [6]. The overall tagging efficiency is $(39.5 \pm 0.7)\%$, and the tagging power increases from $(2.43 \pm 0.08 \pm 0.26)\%$ to $(3.37 \pm 0.12 \pm 0.27)\%$; 

2. an updated decay-time acceptance model. For this, the decay channel $B^0 \to J/\psi K^+ (892)^0$, which has a well-known lifetime, is used to calibrate the decay-time acceptance, and simulated events are used to determine a small relative correction between the acceptances for the $B^0_s \to J/\psi K^+ (892)^0$ and $B^0_s \to J/\psi \pi^+ \pi^-$ decays; 

3. the use of the updated values of $\Gamma_s$ and $\Delta \Gamma_s$ from the $B^0 \to J/\psi K^+ K^-$ analysis presented in this paper as constraints in the fit for $\phi_s$.

The measurement of $\phi_s$ using only the $B^0_s \to J/\psi \pi^+ \pi^-$ events is 

$$\phi_s = -(14.0^{+0.17}_{-0.16}) \pm 0.01 \text{ rad},$$

where the systematic uncertainty is obtained in the same way as described in Ref. [6]. The decay-time resolution in this channel is approximately 40 fs, and its effect is included in the systematic uncertainty.

In addition, the effective lifetime $\tau_{B^0_s \to J/\psi \pi^+ \pi^-}$ is measured by fitting a single exponential function to the $B^0_s$ decay-time distribution with no external constraints on $\Gamma_s$ and $\Delta \Gamma_s$ applied. The result is

$$\tau_{B^0_s \to J/\psi \pi^+ \pi^-} = 1.652 \pm 0.024(\text{stat}) \pm 0.024(\text{syst}) \text{ ps}.$$

This is equivalent to a decay width of

$$\Gamma_{B^0_s \to J/\psi \pi^+ \pi^-} = 0.605 \pm 0.009(\text{stat}) \pm 0.009(\text{syst}) \text{ ps}^{-1},$$

which, in the limit $\phi_s = 0$ and $|\lambda| = 1$, corresponds to $\Gamma_H$. This result supersedes that reported in Ref. [46]. The uncertainty on the $B^0$ lifetime [11] used to calibrate the decay-time acceptance is included in the statistical uncertainty. The remaining systematic uncertainty is evaluated by changing the background model and assigning half of the relative change between the fit results with and without the decay-time acceptance correction included, leading to uncertainties of 0.011 ps and 0.021 ps, respectively. The total systematic uncertainty obtained by adding the two contributions in quadrature is 0.024 ps.

XII. COMBINED RESULTS FOR $B^0_s \to J/\psi K^+ K^-$ AND $B^0_s \to J/\psi \pi^+ \pi^-$ DATA SETS

This section presents the results from a simultaneous fit to both $B^0_s \to J/\psi K^+ K^-$ and $B^0_s \to J/\psi \pi^+ \pi^-$ data sets. The joint log likelihood is minimized with the common parameters being $\Gamma$, $\Delta \Gamma_s$, $\phi_s$, $|\lambda|$, $\Delta m_s$, and the tagging
calibration parameters. The combined results are given in Table XII. The correlation matrix for the principal parameters is given in Table XIII.

For all parameters, except $\Gamma_s$ and $\Delta \Gamma_s$, the same systematic uncertainties as presented for the stand-alone $B^0 \to J/\psi K^+ K^-$ analysis are assigned. For $\Gamma_s$ and $\Delta \Gamma_s$, additional systematic uncertainties of 0.001 ps$^{-1}$ and 0.006 ps$^{-1}$, respectively, are included, due to the $B^0 \to J/\psi \pi^+ \pi^-$ background model and decay-time acceptance variations described above.

XIII. CONCLUSION

A sample of $p p$ collisions at $\sqrt{s} = 7$ TeV, corresponding to an integrated luminosity of 1.0 fb$^{-1}$, collected with the LHCb detector is used to select $27617 \pm 115 B^0 \to J/\psi K^+ K^-$ events in a $\pm 30$ MeV/c$^2$ window around the $\phi(1020)$ meson mass [11]. The effective tagging efficiency from the opposite-side (same-side kaon) tagger is $\varepsilon_{\text{eff}} = 2.29 \pm 0.22\%$ (0.89 $\pm$ 0.18$\%$). A combination of data- and simulation-based techniques is used to correct for detector efficiencies. These data have been analyzed in six bins of $m(K^+ K^-)$, allowing the resolution of two symmetric solutions, leading to the single most precise measurements of $\phi_s$, $\Gamma_s$, and $\Delta \Gamma_s$:

$$\phi_s = 0.07 \pm 0.09(\text{stat}) \pm 0.01(\text{syst}) \text{rad},$$

$$\Gamma_s = 0.663 \pm 0.005(\text{stat}) \pm 0.006(\text{syst}) \text{ps}^{-1},$$

$$\Delta \Gamma_s = 0.100 \pm 0.016(\text{stat}) \pm 0.003(\text{syst}) \text{ps}^{-1}.$$

The $B^0 \to J/\psi K^+ K^-$ events also allow an independent determination of $\Delta m_s = 17.70 \pm 0.10 \pm 0.01$ ps$^{-1}$.

The time-dependent $CP$-asymmetry measurement using $B^0 \to J/\psi \pi^+ \pi^-$ events from Ref. [6] is updated to include same-side kaon tagger information. The result of performing a combined fit using both $B^0 \to J/\psi K^+ K^-$ and $B^0 \to J/\psi \pi^+ \pi^-$ events gives

$$\phi_s = 0.01 \pm 0.07(\text{stat}) \pm 0.01(\text{syst}) \text{rad},$$

$$\Gamma_s = 0.661 \pm 0.004(\text{stat}) \pm 0.006(\text{syst}) \text{ps}^{-1},$$

$$\Delta \Gamma_s = 0.106 \pm 0.011(\text{stat}) \pm 0.007(\text{syst}) \text{ps}^{-1}.$$

The measurements of $\phi_s$, $\Delta \Gamma_s$, and $\Gamma_s$ are the most precise to date and are in agreement with SM predictions [2,41]. All measurements using $B^0 \to J/\psi K^+ K^-$ decays supersede our previous measurements reported in Ref. [5], and all measurements using $B^0 \to J/\psi \pi^+ \pi^-$ decays supersede our previous measurements reported in Ref. [6]. The $B^0 \to J/\psi \pi^+ \pi^-$ effective lifetime measurement supersedes that reported in Ref. [46]. The combined results reported in Ref. [6] are superseded by those reported here. Since the combined results for $\Gamma_s$ and $\Delta \Gamma_s$ include all lifetime information from both channels, they should not be used in conjunction with the $B^0 \to J/\psi \pi^+ \pi^-$ effective lifetime measurement.

ACKNOWLEDGMENTS

We express our gratitude to our colleagues in the CERN accelerator departments for the excellent performance of the LHC. We thank the technical and administrative staff at the LHCb institutes. We acknowledge support from CERN and from the national agencies: CAPES, CNPq, FAPERJ, and FINEP (Brazil); NSFC (China); CNRS/IN2P3 and Region Auvergne (France); BMBF, DFG, HGF, and MPG (Germany); SFI (Ireland); INFN (Italy); FOM and NWO (The Netherlands); SCSR (Poland); ANCS/IFA (Romania); MinES, Rosatom, RFBR, and NRC “Kurchatov Institute” (Russia); MinECo, XuntaGal, and GENCAT (Spain); SNSF and SER (Switzerland); NAS Ukraine (Ukraine); STFC (United Kingdom); and NSF (USA). APPENDIX: DEFINITION OF HELICITY DECAY ANGLES

The helicity angles can be defined in terms of the momenta of the decay particles. The momentum of particle \(a\) in the center-of-mass system of \(S\) is denoted by \(\vec{p}_a\). With this convention, unit vectors are defined along the helicity axis in the three center-of-mass systems and the two unit normal vectors of the \(K^+\ K^-\) and \(\mu^+\ \mu^-\) decay planes as

\[
\hat{\vec{e}}^\mu \mu = \frac{\vec{p}_K^\mu + \vec{p}_\mu^\mu}{|\vec{p}_K^\mu + \vec{p}_\mu^\mu|}, \quad \hat{\vec{e}}_z = \frac{\vec{p}_K^z + \vec{p}_\mu^z}{|\vec{p}_K^z + \vec{p}_\mu^z|},
\]

\[
\vec{\hat{n}}_{KK} = \frac{\vec{p}_K^{KK} \times \vec{p}_\mu^{KK}}{|\vec{p}_K^{KK} \times \vec{p}_\mu^{KK}|}, \quad \vec{\hat{n}}_{\mu \mu} = \frac{\vec{p}_K^{\mu \mu} \times \vec{p}_\mu^{KK}}{|\vec{p}_K^{\mu \mu} \times \vec{p}_\mu^{KK}|}.
\]  

(A1)

The helicity angles are defined in terms of these vectors as

\[
\cos \theta_K = \vec{\hat{n}}_{KK} \cdot \hat{\vec{e}}_{KK}, \quad \cos \theta_\mu = \vec{\hat{n}}_{\mu \mu} \cdot \hat{\vec{e}}_{\mu \mu},
\]

\[
\cos \varphi_h = \vec{\hat{n}}_{KK} \cdot \vec{\hat{n}}_{\mu \mu}, \quad \sin \varphi_h = (\vec{\hat{n}}_{KK} \times \vec{\hat{n}}_{\mu \mu}) \cdot \hat{\vec{e}}_{KK},
\]
