Second primary cancer risk - the impact of applying different definitions of multiple primaries: results from a retrospective population-based cancer registry study

Aishah Coyte¹, David S Morrison² and Philip McLoone^{2*}

Abstract

Background: There is evidence that cancer survivors are at increased risk of second primary cancers. Changes in the prevalence of risk factors and diagnostic techniques may have affected more recent risks.

Methods: We examined the incidence of second primary cancer among adults in the West of Scotland, UK, diagnosed with cancer between 2000 and 2004 (n = 57,393). We used National Cancer Institute Surveillance Epidemiology and End Results and International Agency for Research on Cancer definitions of multiple primary cancers and estimated indirectly standardised incidence ratios (SIR) with 95% confidence intervals (CI).

Results: There was a high incidence of cancer during the first 60 days following diagnosis (SIR = 2.36, 95% CI = 2.12 to 2.63). When this period was excluded the risk was not raised, but it was high for some patient groups; in particular women aged <50 years with breast cancer (SIR = 2.13, 95% CI = 1.58 to 2.78), patients with bladder (SIR = 1.41, 95% CI = 1.19 to 1.67) and head & neck (SIR = 1.93, 95% CI = 1.67 to 2.21) cancer. Head & neck cancer patients had increased risks of lung cancer (SIR = 3.75, 95% CI = 3.01 to 4.62), oesophageal (SIR = 4.62, 95% CI = 2.73 to 7.29) and other head & neck tumours (SIR = 6.10, 95% CI = 4.17 to 8.61). Patients with bladder cancer had raised risks of lung (SIR = 2.18, 95% CI = 1.62 to 2.88) and prostate (SIR = 2.41, 95% CI = 1.72 to 3.30) cancer.

Conclusions: Relative risks of second primary cancers may be smaller than previously reported. Premenopausal women with breast cancer and patients with malignant melanomas, bladder and head & neck cancers may benefit from increased surveillance and advice to avoid known risk factors.

Keywords: Second primary cancer, Relative risk, Survival, Scotland, Cancer registry

Background

The prevalence of patients living after a diagnosis of cancer has increased due to rising incidence and improving survival [1-3]. Patients often seek information on preventing and detecting further cancer occurrence [4,5]. There is therefore an increasing need to determine the risk of subsequent cancer and to provide appropriate surveillance and behaviour modification advice.

The risk of further primary cancers might be expected to be raised because of persisting effects of genetic and

behavioural risk factors, long term side-effects of chemo- and radiotherapy, and increased diagnostic sensitivity. There is some evidence that this is the case [6]. For female breast cancer, the risk of contralateral breast cancer is 3% after 5 years [7] a four-fold increase [8,9]. Risks of second primary colorectal cancers are doubled [10] but might only be increased in tumours of the proximal colon [11]. A five-fold increase in risk of primary lung cancers following Hodgkin's lymphoma has been reported [12] and risks of second primary head & neck cancers are raised [13].

A new evaluation of second primary cancer risk is needed for several reasons. There have been significant temporal changes in the prevalence of risk factors – such

as smoking [14], alcohol consumption [15] and obesity [16] - which may affect cancer incidence among survivors of cancer. Diagnostic sensitivity has increased due to screening programmes [17,18] and the increased use of medical imaging technologies [19,20]. Registries use various rules to distinguish between cancers that are new cases and those that are an extension of an existing cancer. The criteria for defining second primary cancers have changed over time and differ between studies. Two sets of rules are widely used; the rules of the Surveillance Epidemiology and End Results (SEER) Program [21] are used mainly by North American cancer registries; the rules developed by the International Association of Cancer Registries (IACR) and the International Agency for Research on Cancer (IARC) [22,23] are used internationally, mainly for reporting. SEER takes account of histology, site, laterality and time since initial diagnosis to identify multiple primary cancers. The IARC/IACR rules are more exclusive; only one tumour is registered for an organ, irrespective of time, unless there are histological differences.

Our aim was to describe second primary cancers in a large geographically defined population over a period when increasing detection, greater diagnostic sensitivity and improved survival may have altered previous estimates of risk. We used Scottish cancer registry data, which have a high case ascertainment rate for most tumour types [24-26], and applied comprehensive and restricted definitions of second primary cancers.

Methods

Population

Using the Scottish Cancer Registry we identified all patients resident in the West of Scotland (population 2.4 million), aged ≥ 15 years who had a first diagnosis of a malignant primary cancer between January 2000 and December 2004 ($n = 58,364$). Diagnoses were coded to the International Classification of Diseases 10th revision (ICD-10). We ignored registrations of non-melanoma skin cancers (ICD-10 C44). A cancer was deemed to be a first incident, or index, cancer if there was no prior record of cancer since 1980 and the cancer was recorded as a malignant primary cancer (International Classification of Diseases for Oncology behaviour code 3). We excluded patients whose index cancer was diagnosed at date of death ($n = 965$). Six patients were excluded because date of death was recorded as preceding date of incidence. The final sample comprised 57,393 patients. We excluded the first sixty days of follow up from the main analysis because it is difficult to distinguish between synchronous and metachronous tumours during this period.

When cancer occurred at the same index cancer site we recorded the subsequent cancer as a primary cancer according to International Agency for Research on

Cancer/International Association of Cancer Registries (IACR/IARC) rules [22,23] and also Surveillance Epidemiology and End Results (SEER) rules for reporting multiple primaries. We applied IARC/IACR rules using IARCcrgTools [27]. IARC/IACR only allow one tumour (depending on histologic group) per organ or pair of organs per person per lifetime. SEER rules were applied using the multiple primary and histology coding manual [28]. SEER rules take account of histology, site, laterality and time since diagnosis.

Statistical methods

The relative risk of a second primary cancer was estimated by indirect standardisation. The person-years at risk among patients diagnosed with a first primary cancer were calculated from diagnosis until 5 years later, date of death or date of diagnosis of a second primary cancer, whichever came first. Data were stratified by site of first primary cancer, site of second primary cancer, sex and age at first diagnosis. The expected number of second cancers in each stratum was estimated by multiplying the total number of person-years by the age, sex and cancer specific incidence rate in the population of the West of Scotland in each year between 2000 and 2009. Standardised incidence ratios (SIR) were obtained by dividing the observed number of cases of second primary cancer by the number expected. This provided an estimate of the risk of a cancer patient developing a second primary cancer relative to the incidence of cancer in the West of Scotland general population. Relative risks are presented with exact 95% confidence intervals for Poisson counts. Rates of second cancer incidence were expressed per 100 person-years and age and sex standardised to the European standard population. STATA version 11 (StataCorp, CollegeStation, TX, USA) was used to conduct statistical analyses.

Ethics

Formal ethical approval was unnecessary because the analysis employed routinely collected non-patient identifiable data. The use of these data for research purposes has been approved by the Privacy Advisory Committee to the Board of NHS National Services Scotland.

Results

We identified 57,393 patients with an incident primary cancer. Five percent (2966/57393) were diagnosed with a further primary cancer within 5 years of diagnosis. Sixteen percent of second cancers (487/2966) were diagnosed on the same day as the index cancer. A further 12% (342/2966) were diagnosed between one to sixty days after first diagnosis. The crude rate was 4.0 per 100 person-years in the first sixty days (Table 1). Over the 5 years of follow-up the rate was 2.0 per 100 person-

Table 1 Number of second primary cancers and person-years of follow up

Time since primary cancer diagnosis	Second cancers* (n)	Person-years (years)	Crude rate (per 100 person-years)	Standardised rate† (per 100 person-years)
0 days	487	0	-	-
1- 60 days	342	8605	4.0	2.1
61 days - 1 year	455	33365	1.4	0.7
>1 -5 years	1682	103464	1.6	0.8
0-5 years	2966	145435	2.0	1.0

*excluding non-melanoma skin cancer.
 †age & sex standardised (European standard population ages 15 to 85+).

years. Figure 1 shows the rates expressed as standardised incidence ratios (SIR) for men and women. The risk in the first 60 days was 3 times the population risk for women and 2 times the risk for men. Between 60 days and 1 year risks were lower than the reference population. The overall SIR between 1 day-5 years was 1.07 (95%CI = 1.03 to 1.11) for both sexes combined.

The age, sex and 5-year survival of the 56,564 patients who did not have a cancer in the first 60 days is summarised in Table 2. Forty seven percent were aged 70 and over, sixty one percent died within five years, and 2137 (3.8%) had a second primary cancer.

Table 2 shows there was concordance in the order of first and second primary cancers. Lung cancer comprised 19% and 24% of first and second cancers, respectively; colorectal cancer comprised 13% and 15%; and female breast cancer represented 15% and 11%. Five year survival and the proportion of patients who had a further cancer were associated. One to two percent of patients with cancers with poor survival (6-25% alive at

5 years for lung, oesophagus, ovarian, and stomach cancer) had a further primary cancer. The proportion of second cancers among primary patients with cancers with better survival (37-79% alive at 5 years) ranged from 4% for colorectal to 8.5% for head & neck cancers.

Compared to the distribution of index cancers sites (Table 2), there were higher proportions of head & neck cancers (13% vs. 4% of index cancers) among patients with lung cancer, higher proportions of lung cancer (43% vs. 19%) among head & neck cancer patients, and higher proportions of prostate (28% vs. 9%) and lung cancers (36% vs. 19%) among patients with bladder cancer. $P < 0.0001$ for each comparison.

Later cancers at the same site may be recurrences rather than true primaries. Table 3 shows the number of registered subsequent primary cancers, in the same ICD-10 category as the index cancer, classified by IARC/IACR and SEER rules. In each case SEER included a greater number of second primaries than IARC/IACR. Female breast cancer showed the greatest difference; 79 of 98

[‡]diagnosed >60 days- 5 years after first primary cancer.

subsequent breast cancers were classified as second primaries by SEER but only 1 by IARC. For malignant melanoma, all 28 subsequent melanomas were identified as second primaries by SEER but none by IARC/IACR rules. There was a smaller difference for head & neck cancers, for which SEER and IARC/IACR included 29 and 24 of 32 subsequent head & neck cancers.

Table 4 shows the relative risk of second primary cancers using all registrations, all registrations applying IARC/IACR and SEER rules, and all registrations excluding same site cancers. There was no overall difference in cancer incidence compared to the general population (SIR = 0.96, 95% CI = 0.91 to 1.00; SIR = 0.99, 95% CI = 0.94 to 1.04 excluding same site cancers). IARC/IACR rules, which excluded the largest number of subsequent cancers, suggested a lower risk (SIR = 0.86, 95% CI = 0.81 to 0.90). Patients with lung, colorectal, breast (aged ≥50 years), prostate and ovarian cancers were at lower risk of further cancers compared with the general population. IARC/IACR and SEER rules reduced the estimated risks further. Patients with cancers of the head & neck, bladder, and breast (women aged <50 years) showed statistically significant raised rates of subsequent cancers. Patients with malignant melanoma had raised risks of second cancers using all registrations and SEER rules; however, IARC/IACR rules suggested no excess risk.

Figures 2 and 3 shows SIRs for 13 common second or further primaries within 5 years of first diagnosis of lung, colorectal, breast, prostate, bladder and head & neck

cancer. SIRs based on IARC/IACR and SEER rules are also shown. For primary lung cancer, lower risks of colorectal cancer (SIR = 0.53, 95% CI = 0.26 to 0.94) and higher risks of head & neck cancers (SIR = 2.60, 95% CI = 1.45 to 4.28) were observed (Figure 2). When IARC/IACR and SEER rules were applied, the risk of subsequent lung cancer was significantly lower. For primary colorectal cancers there were no significant differences in risk for each cancer compared to the reference population, although there was a suggestion of an increased risk of endometrial cancer (SIR = 1.95, 95% CI = 0.89 to 3.71). Applying IARC/IACR, but not SEER, rules reduced the estimated risk of subsequent colorectal cancer. Prostate cancer patients experienced lower rates of lung (SIR = 0.81, 95% CI = 0.65 to 1.00), oesophageal (SIR = 0.55, 95% CI = 0.26 to 1.01) and prostate cancers (SIR = 0.03, 95% CI = 0.01 to 0.09), and a non-significant higher rate of melanoma (SIR = 1.38, 95% CI = 0.76 to 2.32). Women with primary breast cancers also had a non-significant raised risk of malignant melanoma (SIR = 1.64, 95% CI = 0.96 to 2.63). Risks of second primary breast cancers were no different from the reference population but estimates were significantly lower (SIR = 0.01, 95% CI = 0 to 0.06) applying IARC rules. Among head & neck patients (Figure 3) there were significantly raised risks of lung cancers (SIR = 3.75, 95% CI = 3.01 to 4.62), oesophageal (SIR = 4.62, 95% CI = 2.73 to 7.29) and head & neck cancers (SIR = 6.10, 95% CI = 4.17 to 8.61). SEER or IARC/IACR rules did not significantly change SIRs for second head & neck cancers. Patients with primary bladder cancers had raised risks of cancers of the lung (SIR = 2.18, 95% CI = 1.62 to 2.88) and prostate (SIR = 2.41, 95% CI = 1.72 to 3.30).

Standardised incidence ratios for selected cancers are shown in Table 5. Between 60 days and 1 year after diagnosis, rates of second primary cancers were generally lower than the reference population. When either IARC/IACR or SEER rules were applied, rates of second primary cancers were lower than rates based on all registrations. Among patients alive one year after diagnosis, risks of further cancers were raised in women with breast cancer aged ≥50 years (SIR = 2.32, 95% CI = 1.71 to 3.07) and patients with head & neck cancers (SIR = 2.10, 95% CI = 1.80 to 2.44). Risks of cancers among prostate cancer survivors at 1 year were significantly lowered (SIR = 0.69, 95% CI = 0.61 to 0.78). One-to-five-year risks were similar to the general population among patients with cancers of the lung, colorectum and breast (aged ≥50 years) although IARC exclusions meant that risks were significantly lowered in patients with colorectal and breast cancers (aged ≥50 years).

Discussion

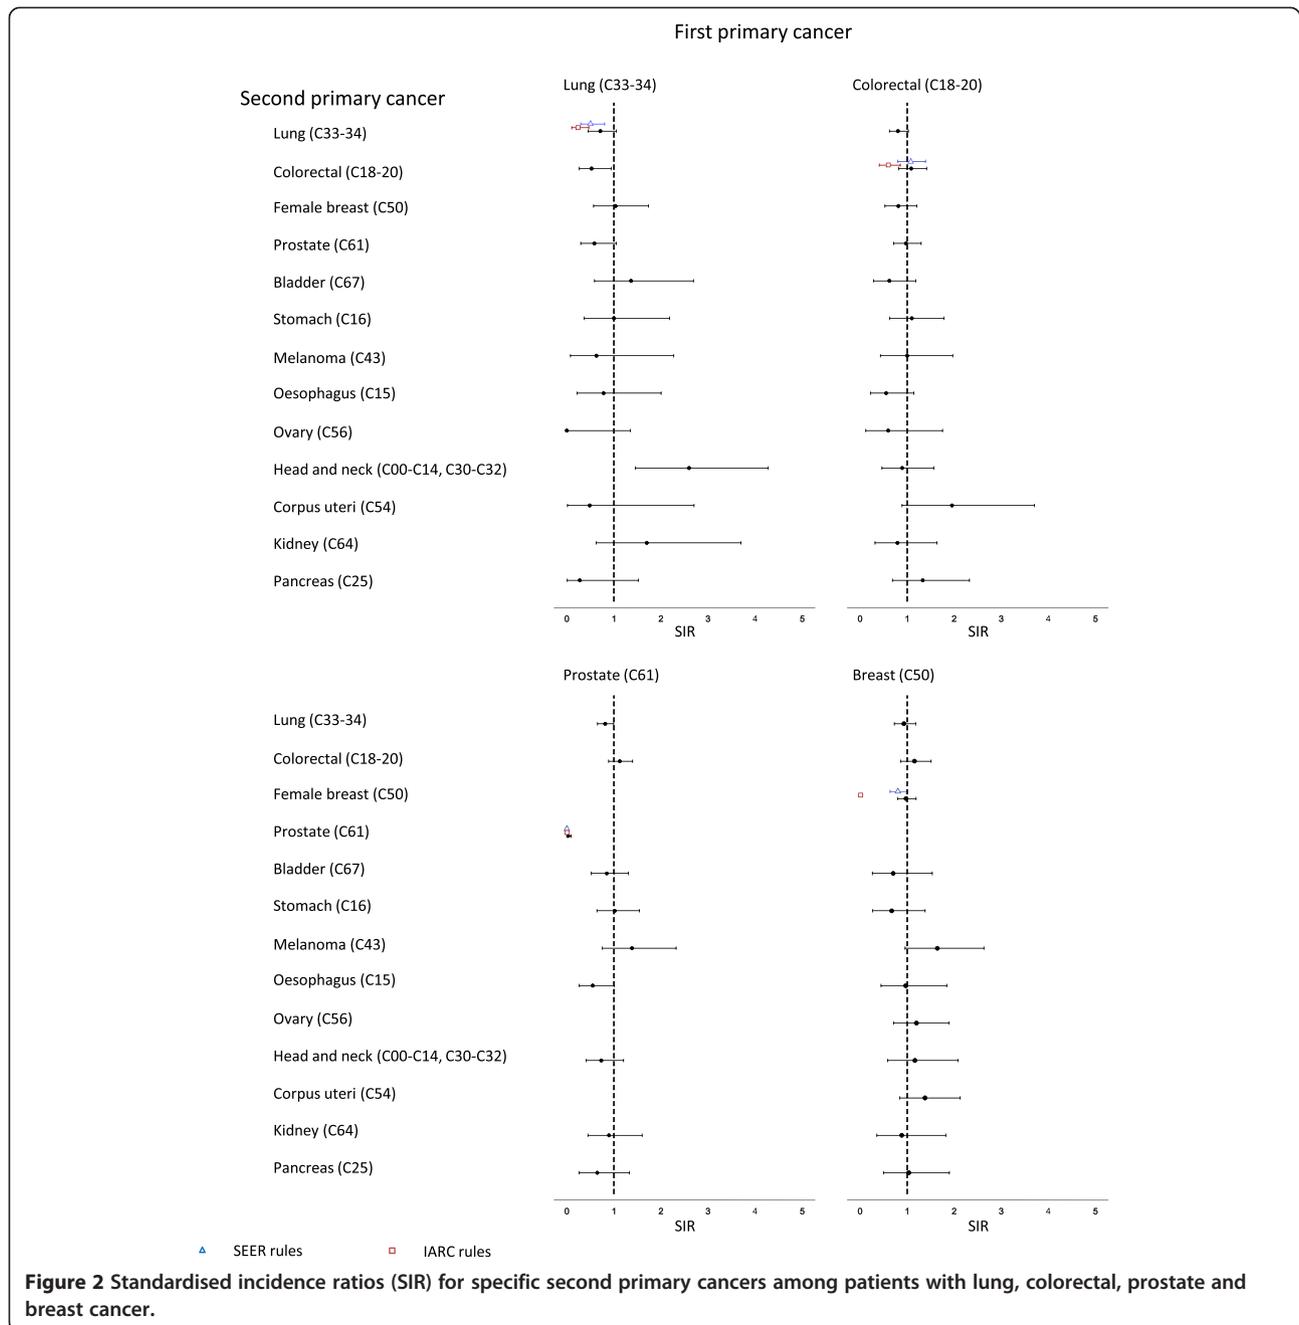

We found an overall raised risk of second primary cancer among patients with a first malignancy (SIR = 1.07).

There was no overall increase in risk when the first sixty days were excluded. However, the risk was raised for patients with specific cancers. Women aged <50 years with cancer of the breast and patients with melanoma, bladder and head & neck cancers were at increased risk. Patients with lung cancer were at increased risk of subsequent head & neck cancers and patients with head & neck cancers were at increased risk of lung cancer, as well as oesophageal and other head & neck tumours. Patients with bladder cancers were at increased risk of lung and prostate cancer.

Studies have reported relative risks of second primary cancers ranging from 1.08 to 1.3 [6,29-31]. Patients with cancer may be at increased risk of further primary cancers for three main reasons: they are subject to intensive investigations and ongoing surveillance; genetic and behavioural risk factors for the initial cancer may persist; and treatment, particularly radiotherapy and chemotherapy, may increase the risk of future malignancies.

We found a raised risk of second cancer diagnosis during the first 60 days, suggesting an artefact of investigation. Crocetti observed a similar overall raised risk to

ours (SIR = 1.08) which was lost when cancers detected in the first two months were excluded [31]. However, Youlden observed larger risks (SIRs of 1.2 and 1.4 in men and women, respectively) which remained 10 years later [30]. Curtis found that raised risks were greatest in recent years (1995–2000) which may reflect increasingly sensitive diagnostic investigation [6].

The most prevalent lung cancer risk factor is cigarette smoking. This could explain the increased risk of other smoking-related cancers among patients with lung or head & neck cancer [32]. A similar association may explain the increase in lung cancer found among patients with bladder cancer. However, clinical investigation of abnormalities in anatomically adjacent sites is likely to

Table 5 Standardised incidence ratios of second primary cancer by time since diagnosis

increase detection and this could explain the excess of prostate cancers found among patients with bladder cancer. Fabbri suggested this for increased prostate and kidney cancers among men with bladder cancer [33,34].

Mellemkjaer reported an SIR of 1.25 for all cancers in women with a primary breast cancer [35]. We found an SIR of 2.13 among women aged <50 years with breast cancer, but applying the same IARC/IACR rules as Mellemkjaer, we observed no excess risk. Women with breast cancer appeared to have a raised risk of melanoma. There have been reports of increased melanoma among patients with prostate and breast cancer [36]. A confounding factor is that prostate and breast cancers have relatively high survival and incidence is highest among socio-economic well-off groups, as is melanoma. Patients with an index cutaneous melanoma are at increased risk of second primary melanomas [37]. This is most likely due to the multifocal effects of ultraviolet light exposure on the skin.

Our finding that patients with lung, colorectal, female breast (ages ≥ 50 years), prostate and ovarian cancer had lower than expected numbers of later cancers is not consistent with previous reports [38-40]. This may be because we excluded cancers in the first two months, when rates have been found to be highest. Cancers detected within two months of the index cancer may otherwise have not been diagnosed until sometime later, if at all.

Our study covered a large population with a high incidence of cancer and used recent cancer registry data. Most tumour registries collect data on only malignant and in situ neoplasms. The Scottish Cancer Registry collects information on all new cases of cancer including primary malignant neoplasms, carcinoma in situ, neoplasms of uncertain behaviour and benign brain and spinal cord tumours. The guidelines for registering multiple primary cancers are not as restrictive as the IARC/IACR rules, although they have some features in common. As a general rule clinical/pathological opinions of second primary cancers are registered. IARC/IACR rules are generally used for reporting purposes. We applied both SEER and IARC/IACR rules, and explored the effect of excluding certain subsequent cancers. We did find there were cancers recorded in the registry that would be excluded as primary tumours according to IARC/IACR rules. We do not know how many additional notifications might have been included using SEER rules but were never entered onto the registry. The IARC/IACR rules may undercount multiple tumours, because cancers with the same site and histology, diagnosed more than 2 months apart but excluded as a later primary, may actually represent a new tumour. However to include these cancers could over count multiple tumours. Conversely, a new primary cancer may be

misdiagnosed as a recurrence or metastasis. Our registry data found that 5% of cancer patients had a registration of a second primary cancer within 5 years. In contrast a study in the Netherlands, where the longest follow up time was 18 years, found that the percentage of patients who had a second cancer was 6% [41]. This difference might be due to differences in registration practice.

We found a similar absolute risk to others, suggesting that the smaller relative risk may be due to changing incidence in the general, comparator population. Screening programmes and initiatives to improve public awareness of cancer have contributed to greater detection; expected rates have risen and the relative risk for patients with an index cancer may have fallen. We did not have information on genetic risk factors, such as BRCA1, that might identify clusters of cancers in high risk individuals.

Patients with head & neck cancers and women <50 years old with breast cancer are at increased risk of subsequent malignancies. The pattern of second cancers was similar to that of first cancers and thus the advice to minimise exposures to the 14 lifestyle and environmental factors described by Parkin [42] remains valid. Further research is needed to determine the effects of behaviour change and previous exposure on subsequent risk. The higher rate of malignant melanoma among patients with breast and prostate cancer requires further investigation. Breast and prostate cancer are socio-economically patterned and higher rates could be due to healthcare seeking behaviour which increases detection or, in the case of melanoma, to increased sun exposure in more affluent patients. Analysis of recent second primary cancer rates in other countries is needed to test these hypotheses.

Conclusion

The relative risk of second primary cancers may be smaller than previously reported, possibly because the general population is subject to greater surveillance and screening. Premenopausal women with breast cancer and patients with malignancies of the bladder, head & neck, and cutaneous melanoma are at increased risk of second primary cancers. It may be appropriate to offer surveillance and advice to avoid known risk factors to these patients. Further research is needed to determine whether previous perspectives of increased second primary cancer risks have been partly due to differences in detection.
