#### 24 ABSTRACT

25 The neural processing of a visual stimulus can be facilitated by attending to its position or by 26 a co-occurring auditory tone. Using frequency-tagging we investigated whether facilitation 27 by spatial attention and audio-visual synchrony rely on similar neural processes. Participants 28 attended to one of two flickering Gabor patches (14.17 and 17 Hz) located in opposite lower 29 visual fields. Gabor patches further "pulsed" (i.e. showed smooth spatial frequency 30 variations) at distinct rates (3.14 and 3.63 Hz). Frequency-modulating an auditory stimulus at 31 the pulse-rate of one of the visual stimuli established audio-visual synchrony. Flicker and 32 pulsed stimulation elicited stimulus-locked rhythmic electrophysiological brain responses 33 that allowed tracking the neural processing of simultaneously presented stimuli. These 34 steady-state responses (SSRs) were quantified in the spectral domain to examine visual 35 stimulus processing under conditions of synchronous vs. asynchronous tone presentation 36 and when respective stimulus positions were attended vs. unattended. Strikingly, unique 37 patterns of effects on pulse- and flicker driven SSRs indicated that spatial attention and 38 audiovisual synchrony facilitated early visual processing in parallel and via different cortical 39 processes. We found attention effects to resemble the classical top-down gain effect 40 facilitating both, flicker and pulse-driven SSRs. Audio-visual synchrony, in turn, only 41 amplified synchrony-producing stimulus aspects (i.e. pulse-driven SSRs) possibly highlighting 42 the role of temporally co-occurring sights and sounds in bottom-up multisensory integration. 43

44

## 45 **1. INTRODUCTION**

46	Behavioral goals, as well as the physical properties of sensory experiences, shape how neural
47	processes organize the continuous and often rich influx of sensory information into
48	meaningful units. One such process, selective attention, serves to prioritize currently
49	behaviorally relevant sensory input while attenuating irrelevant aspects (Posner et al., 1980;
50	Treisman and Gelade, 1980). In a visual search display, for example, items matching the
51	color or orientation of a pre-defined target stimulus undergo prioritized processing relative
52	to other items (Treisman and Gelade, 1980; Wolfe, 1994; Wolfe et al., 1989).
53	Another process exploits the spatial and temporal structure of dynamic sensory input,
54	extracting regularities either in the visual modality alone (Alvarez and Oliva, 2009; Lee, 1999)
55	or, by cross-referencing co-occurrences across sensory modalities (Fujisaki and Nishida,
56	2005). In fact, aforementioned visual search can be drastically improved by presenting a
57	spatially uninformative tone pip that coincides (repeatedly) with a sudden change in target
58	appearance in a dynamic search array (Van der Burg et al., 2008).
59	This pop-out effect has been ascribed to a gain in relative salience of the target stimulus
60	caused by the unique integration of auditory and visual information. The impression of a
61	multisensory object hereby hinges on the temporal precision of coinciding unisensory inputs,
62	also termed audio-visual synchrony, a critical cue for multisensory integration (Werner and
63	Noppeney, 2011). Consecutive synchronous co-occurrences of the same auditory and visual
64	stimulus components further increase the likelihood of multisensory integration (Parise,
65	2012).
66	Generalizing this multisensory effect to our everyday experience of dynamic cluttered visual

67 scenes, Talsma et al (2010) put forward that multisensory objects tend to involuntarily

68 attract attention towards their position. As a consequence, they would gain an automatic

- 69 processing advantage over unisensory stimuli. In a task that requires a sustained focus of
- 70 attention on a specific position in the visual field multisensory stimuli may then act as strong

	ACCLI ILD MANUSCHII I
71	distractors (Krause et al., 2012) because they withdraw common processing resources from
72	the task-relevant focus of attention.
73	Interestingly, this influence seems to work both ways: As Alsius et al. (2005) have shown
74	focusing on a visual task impedes the integration of concurrent but irrelevant visual and
75	auditory input. This effect has been related to the concept of the temporal binding window,
76	a period during which co-occurring attended visual and auditory stimuli are most likely to be
77	integrated (Colonius and Diederich, 2012). The window can expand for stimuli appearing at
78	attended locations but remains unaffected (or contracts) when spatial attention is averted
79	(Donohue et al., 2015).
80	Both phenomena - the involuntary orientation of spatial attention towards multisensory
81	events as well as impeded multisensory integration when maintaining focused attention -
82	have largely been studied in isolation (Talsma et al., 2010). We frequently encounter
83	situations, however, in which the two biases can act concurrently. Moreover, they may
84	fluctuate between having conjoined and conflicting effects depending on whether attended
85	positions and multisensory events overlap or diverge in the visual field (that is in addition to
86	their own inherent temporal variability (Keil et al., 2012).
87	This complex interplay therefore warranted a dedicated investigation in a paradigm that
88	allowed contrasting both cases directly. In the present study, we manipulated trial by trial
89	whether participants attended to a dynamic audio-visual synchronous stimulus while leaving
90	a concurrently presented asynchronous stimulus unattended or vice versa.
91	We probed early cortical visual processing by tagging stimuli with distinct temporal
92	frequencies (Norcia et al., 2015; Regan, 1989). This frequency-tagged stimulation elicited
93	periodic brain responses, termed steady-state responses (SSRs). SSRs index continuous
94	processing of individual stimuli in multi-element displays and have been demonstrated to
95	indicate the allocation of spatial attention (Kim et al., 2007; Müller et al., 1998a; Walter et

96	al., 2012) as well as audio-visual synchrony (Jenkins et al., 2011; Keitel and Müller, 2015;
97	Nozaradan et al., 2012).
98	Crucially, employing frequency-tagging allowed us to tease apart the relative facilitating
99	effects of both factors as follows: Our paradigm featured two Gabor patches, one per lower
100	visual hemifield, that each displayed two rhythmic physical modulations: As in classical
101	frequency-tagging experiments they displayed a simple on-off flicker at different rates
102	(14.17 and 17 Hz, respectively). Additionally, spatial frequencies of the Gabor patches
103	modulated at slower rates (3.14 and 3.62 Hz, respectively), which gave the impression of a
104	pulsation-like movement (see Figure 1). We exploited this pulsation to introduce audio-
105	visual synchrony with a concurrently presented tone that carried a frequency modulation
106	with the same temporal profile as one of the visual stimulus' movement (Giani et al., 2012;
107	Hertz and Amedi, 2010 for similar approaches; see Keitel and Müller, 2015). Participants
108	were then cued randomly on each trial to attend to one of the two stimulus positions, while
109	one of the two Gabor patches pulsed in synchrony with the tone. This paradigm enabled
110	comparisons of SSR-indexed visual processing between four cases of Gabor patch
111	presentation: attended synchronous (A+S+), attended asynchronous (A+S-), unattended
112	synchronous (A-S+) and unattended asynchronous (A-S-).
113	We expected our data to replicate well-described gain effects of top-down cued spatial
114	attention on flicker-driven SSRs (Keitel et al., 2013; Kim et al., 2007; Müller et al., 1998a).
115	Further, we assumed that these gain effects extend to pulsation-driven SSRs, because spatial
116	attention should prioritize any information presented at an attended location.
117	Secondly, we hypothesized that in line with previous findings (Nozaradan et al., 2012) audio-
118	visual synchrony produced gain effects on SSRs. In contrast to attentional gain, results of an
119	earlier investigation suggested that synchrony-related gain effects may be specific to
120	pulsation-driven SSRs. Using a paradigm similar to the present study, Keitel and Müller
121	(2015) found that an SSR component with a frequency of twice the pulsation rate was

122 exclusively susceptible to synchrony-related gain effects. At this rate, the stimulation 123 presumably contained strong transients critical for establishing audio-visual synchrony 124 (Werner and Noppeney, 2011). If that were the case the current paradigm was expected to 125 produce similarly selective effects. Alternatively, however, if audio-visual synchrony simply 126 attracted spatial attention, then synchrony-related facilitation should mirror the pattern of 127 attention-related gain effects on pulse- and flicker-driven SSRs. More specifically, synchrony 128 alone should produce gain effects for flicker-driven SSRs. 129 Comparable patterns of attention- and synchrony-related facilitation would further point 130 towards an account in which they may draw upon similar resources and therefore interact in 131 facilitating visual processing: An attended stimulus would benefit less from audio-visual 132 synchrony compared with an unattended synchronous stimulus, because attention has 133 already been allocated to its position. Conversely, if attention- and synchrony-related 134 facilitation relied on distinct neural resources, they were assumed to have independent 135 additive effects on SSRs. 136 The latter finding could then be cast in a framework in which spatial attention biases are 137 conveyed top-down via a fronto-parietal cortical network (Corbetta and Shulman, 2002), 138 whereas audio-visual synchrony may have been established bottom-up via direct cortico-

- 139 cortical connections or subcortical relays (Lakatos et al., 2009; van Atteveldt et al., 2014).

141 **2. METHODS** 

142 **2.1.** Participants

We collected data from 14 participants with normal or corrected-to-normal vision and normal hearing. Participants gave informed written consent prior to experiments. None reported a history of neurological diseases or injury. They received course credit or a small monetary compensation for participation. The experiment was conducted in accordance

147	with the Declaration of Helsinki and the guidelines of the ethics committee of the University
148	of Leipzig.
149	Two participants showed excessive eye movements during EEG recordings and were thus
150	excluded. Data of 12 participants aged 18 – 31 years (all right-handed, 9 female) entered
151	analyses. Previous studies have used comparable sample sizes to reliably (re)produce effects
152	of spatial attention (Ding, 2005; Müller et al., 1998a; 1998b; Walter et al., 2015; Zhang et al.,
153	2010) and audio-visual synchrony (Jenkins et al., 2011; Keitel and Müller, 2015; Nozaradan et
154	al., 2012) on SSRs.
155	
156	2.2. Stimulation
157	Stimuli were presented on a 19-inch cathode ray tube screen positioned 0.8 m in front of
158	participants. The screen was set to a refresh rate of 85 frames per second and a resolution of
159	1024 x 768 pixel (width x height). Visual experimental stimulation consisted of two
160	monochrome Gabor patches with a diameter of ~3° of visual angle, one located in the lower
161	left and the other one located in the lower right visual field at eccentricities of 4.5° from
162	vertical and 2.5° from horizontal meridians (see Figure 1a). Stimuli were presented against a
163	grey background (RGB: 128,128,128; luminance = 30 cd/m <sup>2</sup> ). Two black concentric circles (.4°
164	of visual angle outer eccentricity, RGB: 0, 0, 0) in the center of the display served as fixation
165	point.
166	Both Gabor stimuli underwent two independent periodic changes in the course of a trial:
167	(1) The right patch presentation followed a cycle of 4 on-frames and 2 off-frames (2/1
168	on/off-ratio) resulting in a 17 Hz flicker. The left patch flickered at a rate of 14.2 Hz achieved
169	by repetitive cycles of 3 on-frames and 2 off-frames (3/2 on/off-ratio). (2) While flickering,
170	the spatial frequency of the Gabor patches oscillated between a maximum of 2 Hz/° and a
171	minimum of 1 Hz/° at a rate of 3.14 Hz for the right patch and 3.62 Hz for the left patch.
172	Periodic spatial frequency changes gave the impression of alternating contractions and

173	relaxations that led to the percept of pulsing Gabor patches over time (Figure 1c & d). Pulse
174	frequencies were chosen based on pilot experiments that served to determine a trade-off
175	frequency range in which pulsing was readily perceptible, yet, still allowed driving periodic
176	frequency-following brain responses (SSRs).
177	In addition to the visual stimuli we presented a tone with a center frequency of 440 Hz
178	binaurally via headphones. The frequency of the tone was rhythmically modulated following
179	sinusoidal excursions from the center frequency (10% maximum excursion = $\pm$ 44 Hz). On
180	each trial the modulation rate exactly matched the pulse rate of one of the two Gabor
181	patches. Common rhythmic changes over time resulted in sustained audio-visual synchrony
182	(see e.g. Schall et al., 2009).
183	Prior to the experiment, we employed the method of limits (Leek, 2001) to approximate
184	individual hearing thresholds using one of the experimental stimuli, a 3.14-Hz frequency
185	modulated tone (see e.g. Herrmann et al., 2014; Keitel and Müller, 2015). In our
186	implementation, participants listened to a series of 10 tone sequences with a maximum
187	duration of 15 s per sequence. Tone intensity changed during each sequence while
188	alternating between log-linear decreases and increases across sequences. Participants were
189	instructed to indicate by button press when they stopped or started hearing respective
190	tones. Cross-referencing button response times with tone intensity functions yielded
191	individual estimates of psychophysical hearing thresholds, i.e. sensation levels (SL). In the
192	experiment, acoustical stimulation was presented at an intensity of +35 dB SL.
193	
194	2.3. Procedure and Task

Participants were seated comfortably in an acoustically dampened and electromagnetically shielded room and directed gaze towards the fixation ring on the computer screen. At the beginning of each trial, participants were cued to attend exclusively to the left or the right visual stimulus. To this end, a green semi-circle appeared inside the fixation ring for 500 ms

	ACCEPTED MANUSCRIPT
199	to indicate the task-relevant Gabor patch (see Figure 1b). Subsequently, the two pulsing
200	Gabor patches and the tone were presented for 3500 ms. At the end of each trial, the
201	fixation ring remained on screen for an extra 700 ms allowing participants to blink before
202	the next trial started.
203	Participants were instructed to respond to occasionally occurring luminance changes of the
204	cued Gabor patch (= targets) while ignoring similar events in the other patch (= distractors).
205	During such events, Gabor patch luminance faded out to a minimum of 50% and back in
206	within a 300 ms interval. Targets and distractors occurred in 50% of trials and up to 3 times
207	in one trial with a minimum interval of 800 ms between subsequent onsets. Behavioral
208	responses were recorded as space-bar presses on a standard keyboard. The responding
209	hand was changed halfway through the experiment with the starting hand counterbalanced
210	across participants.
211	We manipulated the two factors attended position (left vs. right Gabor patch) and audio-
212	visual synchrony between attended Gabor patch and tone (synchronous vs. asynchronous) in
213	a fully balanced design. Trials of the resulting four conditions – attended synchronous
214	(A+S+), attended asynchronous (A+S-), unattended synchronous (A-S+) and unattended
215	asynchronous (A-S-) – were presented in a pseudo-randomized order. Note that the tone
216	was always in sync with one of the two Gabor patches. Therefore, in the two conditions in
217	which the tone was out of sync with the attended Gabor patch, it was in sync with the
218	unattended patch.
219	In total, we presented 600 trials (= 150 trials per condition) divided into 10 blocks (~5 min
220	each). Before the experiment, participants performed training for at least one block. After
221	each training and experimental block, they received feedback on the average hit rate and

222 reaction time.

223

#### 224 **2.4.** Behavioral data recording and analyses

Responses were considered a 'hit' when the space bar was pressed between 200 to 1000 ms after target onset. We further defined false alarms as responses to distractors within the same time range. Based on these data, we calculated the response accuracy as the ratio of correct responses to the total number of targets and distractors for each condition and participant as follows:

$$230 \quad ACC = \frac{N_{Hits} + N_{Correct Rejections}}{N_{Targets} + N_{Distracters}}$$
[1]

where correct responses (= numerator) are the sum of target hits N<sub>Hits</sub> and correctly rejected

distracters N<sub>Correct Rejections</sub>. Correct rejections were defined as the total number of presented

distracters minus the number of false alarms. Accuracies were subjected to a two-way

234 repeated measures analysis of variances (ANOVA) with factors of *attended position* (left vs.

right Gabor patch) and synchrony (synchronous vs. asynchronous). Response speed,

236 quantified as median reaction times, was analyzed accordingly.

For all repeated measures ANOVAs conducted in this study effect sizes are given as  $\eta^2$  (eta-

238 squared). Where applicable, the Greenhouse–Geisser (GG) adjustment of degrees of

239 freedom was applied to control for violations of sphericity (Greenhouse and Geisser, 1959).

240 Original degrees of freedom, corrected p-values (*P*<sub>GG</sub>) and the correction coefficient epsilon

241 ( $\epsilon_{GG}$ ) are reported.

242 Further Post-hoc tests – two-tailed t-tests for paired comparisons or against zero – were

- 243 applied where necessary. We applied the Holm-Bonferroni procedure to correct *p*-values
- 244 (*P*<sub>HB</sub>) for multiple comparisons (Holm, 1979).

245

#### 246 **2.5. Electrophysiological data recording**

247 EEG was recorded from 64 scalp electrodes that were mounted in an elastic cap using a

- 248 BioSemi ActiveTwo system (BioSemi, Amsterdam, Netherlands) set to a sampling rate of 256
- Hz. Lateral eye movements were monitored with a bipolar outer canthus montage

250 (horizontal electrooculogram). Vertical eye movements and blinks were monitored with a 251 bipolar montage positioned below and above the right eye (vertical electrooculogram). From 252 continuous data, we extracted epochs of 3500 ms starting at audio-visual stimulus onset. In 253 further preprocessing, we excluded 50% of epochs per condition (= 75) that corresponded to 254 trials containing transient targets and distractors (= brief luminance fadings). These 255 contained neural activity caused by processing target stimuli or motor activity due to 256 response button presses that may have biased spectral estimates. Epochs with horizontal 257 and vertical eye movements exceeding  $25 \,\mu V$  (= 2.5° of visual angle), or containing blinks 258 were also discarded. To correct for additional artefacts, such as single noisy electrodes, we 259 applied the 'fully automated statistical thresholding for EEG artefact rejection' (Nolan et al., 260 2010). This procedure corrected or removed epochs with residual artefacts based on 261 statistical parameters of the data. Artefact correction employed a spherical-spline-based 262 channel interpolation. For each participant FASTER interpolated up to 4 electrodes 263 (median = 2) across recordings and an average of up to 5.6 electrodes (minimum = 1.9, 264 median = 3.6) per epoch. Note that epochs with more than 12 artefact-contaminated 265 electrodes were excluded from further analysis. In total, we discarded an average of 15% of 266 epochs per participant and condition. Subsequently, data were re-referenced to average 267 reference and averaged across epochs for each condition and participant, separately. Basic 268 data processing steps such as extraction of epochs from continuous recordings and re-269 referencing made use of EEGLAB (Delorme and Makeig, 2004) in combination with custom 270 routines written in MATLAB (The Mathworks, Natick, MA).

271

#### 272 **2.6. Electrophysiological data analyses**

In our analyses we focused on two neural markers that have been repeatedly demonstrated
to index attentional modulation: SSR amplitudes (Morgan et al., 1996; Müller and Hubner,

275 2002; Quigley and Müller, 2014) and SSR inter-trial phase coherence (ITC, Kashiwase et al.,

2012; Kim et al., 2007; Porcu et al., 2013). Both measures also reflect effects of audio-visual
synchrony on early visual processing (Nozaradan et al., 2012). Approaches to derive
amplitudes and inter-trial phase coherence differ slightly and are thus described separately
below. Both approaches required spectral decompositions of EEG time series for which we
used the Fieldtrip toolbox (Oostenveld et al., 2011).

281

282 2.6.1. SSR power

283 Artefact-free epochs were truncated to segments of 3000 ms that started 500 ms after 284 audio-visual stimulation onset and averaged separately for each EEG sensor, experimental 285 condition and participant. The first 500 ms were omitted in order to exclude event-related 286 potentials to stimulus onset from spectral analyses. From de-trended (i.e. linear trend 287 removed) 3000 ms segments we quantified power (= squared amplitude) spectra by means 288 of Fourier transforms. For the FFT, the 768 data points representing each 3000 ms segment 289 were zero-padded to a length of 8192 (2^13) to achieve a fine-grained spectral resolution 290 (0.0312 Hz).

291 Figure 2a illustrates that our stimulation was effective in driving distinct SSRs: Power spectra 292 pooled across all 64 scalp electrodes and experimental conditions showed clear peaks at the 293 stimulation rates. Notably, spectra revealed strong harmonic responses at twice the pulse 294 frequencies (6.28 and 7.24 Hz). We included these pulse-driven harmonics in further 295 analyses because fundamental and harmonic responses have been hypothesized to reflect 296 different aspects of stimulus processing (Kim et al., 2011; Pastor et al., 2007; Porcu et al., 297 2013) and showed modulation by synchrony in a previous study (Keitel and Müller, 2015). 298 Grand-average topographical distribution of pulse-driven as well as flicker-driven SSR power 299 averaged over conditions showed widespread maxima at parieto-occipital electrode sites 300 (scalp maps in Figure 2a) that are typically observed in experiments with lateralized flicker 301 stimulation (see e.g. Keitel et al., 2013).

- 302 For each participant and condition, SSR amplitudes were averaged across a cluster of 15 303 electrodes covering parieto-occipital maxima (Oz, O1, O2, Iz, I1, I2, POz, PO3, PO4, PO7, PO8, 304 P7, P8, P9, P10; as indicated in left-most scalp map in Figure 2a). Using a unified cluster of 305 electrodes across frequencies & stimuli allowed for a comparable spatial sampling of all SSR 306 components. 307 Amplitudes were further normalized by taking the decadic logarithm, then multiplying it by 308 20, to yield dB-scaled values (termed log-power in the following). All-positive SSR amplitude 309 values typically show a left-skewed distribution across participants. By taking their logarithm 310 we approximated a normal distribution (skew minimized) that better met the requirements 311 of parametric statistical procedures. 312 SSR log power was subjected to four-way repeated measures analysis of variances (ANOVAs) 313 with factors of driving stimulus position (left vs. right hemifield), attention (attended vs. 314 unattended), synchrony (synchronous vs. asynchronous) and SSR component (pulse 1f, pulse 315 2f and flicker 1f). 316 The factor stimulus position had no effect on SSR log power and did not show any interaction 317 with the other factors (see Results). This afforded collapsing normalized power across left 318 and right stimuli, i.e. across pulse frequency following ('pulse 1f') 3.14 Hz and 3.62 Hz, pulse 319 frequency doubling ('pulse 2f') 6.28 and 7.24 Hz, as well as flicker frequency following 320 ('flicker 1f') 14.17 and 17.00 Hz SSRs, respectively, in subsequent analyses. 321 322 2.6.2. SSR inter-trial phase coherence 323 We computed inter-trial phase coherence (Cohen, 2014) based on Fourier transforms of
- 324 artefact-free single trial epochs, truncated to 3000 ms segments (as described above for SSR
- 325 amplitude analyses) according to:

326 
$$ITC(f) = \left| \frac{1}{N} \sum_{n=1}^{N} \frac{c_n(f)}{|c_n(f)|} \right|$$
 [2]

327 where  $c_n(f)$  is the complex Fourier coefficient of trial n at frequency f and |.| indicates the 328 absolute value. Inter-trial phase coherence as a measure of SSR modulation has been 329 introduced to SSR analyses more recently (Kim et al., 2007; Nozaradan et al., 2012) and SSR 330 amplitude and phase coherence have demonstrated different sensitivities to top-down 331 influences on sensory processing (Kashiwase et al., 2012; Porcu et al., 2013). SSR Inter-trial 332 phase coherence can be visualized as spectra that typically display narrow peaks at 333 stimulation frequencies and higher order harmonics (Nozaradan et al., 2012; Ruhnau et al., 334 2016). 335 Similar to SSR amplitudes, ITCs showed broad topographic maxima at parieto-occipital 336 electrode sites. Condition-averaged ITC spectra pooled across the 15-electrode cluster as 337 described above (see section 2.6.1) revealed distinct peaks at the six frequencies of interest 338 (Figure 2b). 339 Pooled ITCs were subjected to a four-way ANOVA with a design identical to SSR amplitude 340 analyses. Note that ITCs were normalized by taking the natural logarithm prior to statistical 341 evaluation. As for SSR log power, we found that ITC was insensitive to the stimulus position 342 (left vs right; see section 3.2.2.), which again afforded collapsing across left- and right-343 stimulus driven in subsequent analyses. 344 2.6.3. Power of the ongoing EEG and SSRs 345 As depicted in Figure 2c, SSRs have very low signal-to-noise ratios when being evaluated on 346 the basis of averaged single-trial power spectra. Instead, these spectra accentuate the 347 typical 1/f<sup>x</sup> profile of power decreasing towards higher frequencies as well as peaks in the 348 vicinity of 10 Hz that are consistent with alpha rhythmic brain activity. In turn, these features 349 are much attenuated in SSR 'evoked' power and ITC spectra (*Figures 2a* and *b*). 350

351 2.6.4. Joint analyses of SSR amplitude and inter-trial phase coherence modulation

352 As laid out in the Results section, both of our manipulations, spatial attention and audio-

- 353 visual synchrony, revealed distinct patterns of effects on SSR amplitudes and ITCs. To further
- 354 characterize and compare these effects we computed an index that expressed attention-
- and synchrony-related amplitude and ITC modulations for each subject and SSR frequency

356 component *f* (pulse 1f, pulse 2f and flicker 1f) according to:

357 
$$AMI_f = \frac{Amp_f^{att} - Amp_f^{ign}}{Amp_f^{att} + Amp_f^{ign}}$$
[3]

This attention modulation index (AMI) expressed the net gain effect of attention. AMIs were calculated for each stimulus individually. *Amp<sup>att</sup>* denotes SSR amplitudes when a stimulus was attended and *Amp<sup>ign</sup>* when the same stimulus was unattended (i.e. ignored). An identically scaled synchrony modulation index (SMI) was computed by contrasting SSR amplitudes between in-sync and out-of-sync conditions. We were thus able to compare both indices directly. Entering ITCs instead of SSR amplitudes into formula (3) yielded ITC-based AMIs and SMIs.

365 ANOVAs carried out for SSR amplitudes and ITC revealed that *attention* and *synchrony* 

366 influenced SSRs additively, i.e. no interaction between these factors was found (see *Results*).

367 This finding justified collapsing AMIs across synchrony conditions and SMIs across attention

368 conditions for each SSR component, separately, in the following analyses. As an example, we

369 pooled the AMIs expressing the gain between synchronous conditions (A+S+ vs A-S+) and

370 asynchronous conditions (A+S- vs A-S-).

Because further analyses rested firmly on the assumption of an absent *attention* \* *synchrony*interaction, we additionally applied a Bayesian inference approach because in contrast to

- 373 the classical frequentist inference it allowed determining the amount of evidence in favor of
- 374 the null hypothesis (*H*<sub>0</sub>: no interaction) explicitly. To this end, we estimated Bayes factors
- 375 (Rouder et al., 2012), i.e. the plausibility of a specific model given the data. First, separately

376	for SSR power and ITC, we determined models based on factors and interactions that turned
377	out significant in ANOVAs. For example, SSR ITC was affected by a linear combination of
378	factors attention + synchrony + (synchrony * SSR component). These models were tested
379	against two alternative models, one including an interaction term (attention * synchrony),
380	and another one including a main effect of stimulus position.
381	The analysis was performed by means of the function anovaBF provided by the R (version
382	3.3.0; R Core Team, 2013) package <i>Bayes factor</i> v0.9.12–2 (Morey et al., 2015). We adopted
383	the Jeffrey-Zellner-Siow (JZS) prior with a standard scaling factor <i>r</i> of .707 (Rouder et al.,
384	2012; 2009; Schönbrodt and Wagenmakers, 2015). Monte-Carlo resampling was based on
385	10 <sup>6</sup> iterations. Participants were considered as random factor. Importantly, Bayesian
386	modelling favored the additive model (attention + synchrony) without an influence of the
387	factor stimulus position (see Results) and further justified calculating AMIs and SMIs while
388	collapsing across left and right stimuli. Results were robust against changing scaling factors.
389	Finally, AMIs and SMIs were entered into a three-way ANOVA with factors of SSR component
390	(pulse 1f, pulse 2f, and flicker 1f), gain type (attention vs synchrony) and gain measure (SSR
391	amplitude vs ITC). Modulation indices were further tested against zero by means of t-tests
392	(corrected for multiple comparisons).
393	→ Insert Figure 2 here

**3**94 **3. RESULTS** 

- 395 **3.1. Behavioral data**
- 396 Participants detected luminance fadings more accurately when attending to left Gabor

397 patches (main effect *attended stimulus*: F(1,11) = 32.30, P < 0.001,  $\eta^2 = 0.579$ ; see *Table 1*).

- 398 Accuracy remained unaffected by in-sync vs. out-of-sync tone presentation (main effect
- 399 *synchrony*: F(1,11) < 1). The interaction of both factors was not significant (F(1,11) < 1).
- 400 Reaction times increased slightly when participants performed the task on in-sync Gabor
- 401 patches (main effect synchrony: F(1,11) = 9.27, P < 0.05,  $\eta^2 = 0.061$ ; see Table 1) but were

- 402 comparable between left and right stimuli (main effect *attended stimulus*: F(1,11) < 1). As for
- 403 accuracy, the interaction of both factors remained negligible (F(1,11) < 1).
- 404 On average participants responded to 7.17% of distractors (median; interquartile range =
- 405 14.00%). Due to their overall low occurrence false alarms were not analysed in detail. Note
- 406 however that they contributed to the here employed accuracy score (see Formula 1).
- 407  $\rightarrow$  Insert Table 1 here
- 408 **3.2. EEG data**
- 409 We focused our analyses on SSR amplitudes and inter-trial phase coherence values (ITCs) to
- 410 evaluate effects of spatial attention and audio-visual synchrony on early visual stimulus
- 411 processing. Each stimulus drove three spectrally distinct SSR components: one at the
- 412 frequency of stimulus pulsation, another one at twice the pulsation rate and a third
- 413 following stimulus flicker (i.e., pulse 1f, pulse 2f and flicker frequencies, respectively).

414

#### 415 *3.2.1. SSR power*

416 SSR power decreased with increasing stimulus presentation rate (main effect SSR

417 *component*: F(2,22) = 55.76,  $P_{GG} < 0.001$ ,  $\varepsilon_{GG} = 0.90$ ,  $\eta^2 = 0.301$ ; also see *Figure 3*) as has been

- 418 documented extensively before (Keitel and Müller, 2015; Porcu et al., 2014). *Figure 3c*
- 419 underlines that amplitudes further varied with the allocation of attention towards stimuli
- 420 (main effect *attention*: F(1,11) = 24.15, P < 0.001,  $\eta^2 = 0.094$ ) and were affected by audio-
- 421 visual synchrony (F(1,11) = 71.01, P < 0.001,  $\eta^2 = 0.067$ ). Amplitudes were comparable for
- 422 left and right stimuli (main effect stimulus position: F(1,11) < 1). A significant SSR
- 423 component \* synchrony interaction (F(2,22) = 37.03,  $P_{GG} < 0.001$ ,  $\varepsilon_{GG} = 0.56$ ,  $\eta^2 = 0.057$ )
- 424 warranted a closer investigation of synchrony effects on specific SSR components. The
- 425 crucial attention \* synchrony interaction (F(1,11) = 1.12, P = 0.313,  $\eta^2 < 0.001$ ) as well as
- 426 other interaction terms remained non-significant (maximum F(2,22) = 2.94, P = 0.074,  $\eta^2 =$
- 427 0.009 for the stimulus position \* SSR component interaction).

	ACCEFTED MANUSCRIFT
428	The ANOVA results suggested a model based on the linear combination of factors attention
429	+ synchrony + SSR component + (synchrony * SSR component). Bayesian inference confirmed
430	that this model was more plausible than the model including an (attention * synchrony)
431	interaction given our data (Bf <sub>additive</sub> / Bf <sub>interactive</sub> = 4.61 $\pm$ 1.31%), as well as a model including a
432	main effect of <i>stimulus position</i> ( $Bf_{additive} / Bf_{additive + stim. pos.} = 7.55 \pm 2.47\%$ ).
433	The SSR component * synchrony interaction originated from overall differences in the effect
434	of synchrony (in-sync minus out-of-sync) on each SSR component that was most pronounced
435	for pulse 2f components and virtually absent for flicker 1f responses (see Figure 4a). Specific
436	contrasts confirmed that pulse 2f SSRs were more susceptible to synchrony effects than
437	pulse 1f components (t(11) = 4.19, $P_{HB}$ < 0.05). Pulse 1f components in turn showed stronger
438	modulation than flicker 1f components (t(11) = 5.02, $P_{HB}$ < 0.05). Lastly, pulse 2f components
439	carried greater synchrony effects than flicker 1f components (t(11) = 7.83, $P_{HB}$ < 0.05).
440	→ Insert Figure 3 here
441	3.2.2. SSR inter-trial phase coherence
442	ITC showed substantial variation with audio-visual synchrony (F(1,11) = $39.48$ , P < $0.001$ ,
443	$\eta^2$ = 0.113) and the allocation of <i>attention</i> (F(1,11) = 23.43, P < 0.001, $\eta^2$ = 0.139) but no
444	effect of SSR component (F(2,22) = 2.24, $P = 0.130$ , $\eta^2 = 0.026$ ) or stimulus position
445	(F(1,11) < 1). A significant SSR component * synchrony interaction (F(2,22) = 16.16,
446	$P_{GG}$ < 0.001, $\varepsilon_{GG}$ = 0.54, $\eta^2$ = 0.064) indicated that some SSR components were more
447	susceptible to effects of audio-visual synchrony than others (Figure 3b and d). Remaining
448	interaction terms, especially the <i>attention</i> $*$ <i>synchrony</i> term (F(1,11) < 1), failed to indicate
449	systematic effects (maximum F(1,11) = 2.80, P = 0.082, $\eta^2$ = 0.014 for the attention * SSR
450	component interaction). Only the synchrony * stimulus position interaction was significant
451	(F(1,11) = 5.05, P = 0.046) but explained a negligible amount of variance in the data
452	( $\eta^2$ = 0.003) and was thus not further investigated. Note that the absence of effects of SSR
453	component, stimulus position or an interaction of both factors on ITC supports a comparable

454 spatial sampling (by averaging across a uniform cluster of 15 parieto-occipital electrodes; see 455 Methods) of all SSR components. 456 Similar to SSR power, Bayesian inference supported the lack of an attention \* synchrony 457 interaction. Comparing additive and interactive models by means of the Bayesian approach 458 showed evidence in favor of the additive model ( $Bf_{additive}$  /  $Bf_{interactive}$  = 4.30 ± 1.98%), again 459 best modelled without an influence of the factor stimulus position (Bfadditive / Bfadditive + stim. pos. 460 = 6.71 ± 0.96%). 461 Figure 4b illustrates that the SSR component \* synchrony interaction stemmed from greater 462 synchrony effects (in-sync minus out-of-sync) on pulse 1f than flicker 1f components 463  $(t(11) = 4.50, p_{HB} < 0.05)$ . Also, synchrony affected pulse 2f ITC more strongly than flicker 1f 464 components (t(11) = 5.06,  $p_{HB}$  < 0.05). Effects between pulse 1f and 2f SSRs were comparable  $(t(11) = 2.09, p_{HB} = 0.19).$ 465

466

467 3.2.3. Attention- vs Synchrony-related gain effects

468 As described in detail in the methods section, we computed indices that expressed SSR 469 attention- and synchrony-related modulation of each SSR component. These modulation 470 indices (AMIs and SMIs) allowed for a direct statistical comparison of the magnitude of 471 attention and synchrony-related gain effects on SSR amplitudes and ITCs. As MI analyses 472 assumed effects of attention and synchrony to be additive, further to the non-significant 473 attention \* synchrony interactions reported above, we estimated the plausibility of additive 474 vs interactive models given our data by using a Bayesian approach. The estimated Bayes 475 factors for SSR power and ITC (see sections 3.2.1. and 3.2.2.) indicated that both results 476 were more than 4 times more likely under the additive than the interactive model. 477 Comparing modulation indices based on SSR amplitudes (Figure 4E) and SSR inter-trial 478 coherence (Figure 4F) revealed that, overall, attention led to stronger gain effects on SSRs 479 than synchrony  $(15.7\% \pm 1.8 \text{ vs } 13.7\% \pm 1.8, \text{ mean} \pm \text{ standard error}; \text{ main effect } qain type:$ 

480	$F(1,11) = 28.79$ , $P < 0.001$ , $\eta^2 = 0.20$ ). Most importantly, however, this difference in gain
481	effects varied between SSR components (interaction gain type * SSR component:
482	$F(2,22) = 6.66$ , $P_{GG} = 0.007$ , $\varepsilon_{GG} = 0.898$ , $\eta^2 = 0.13$ ) in the absence of a modulation of gain
483	effects across SSR components alone (main effect: $F(2,22) = 0.41$ , $P = 0.668$ ).
484	From a methodological perspective it should be noted that power-based modulation
485	indicated a small but significantly higher gain than ITC based modulation (main effect gain
486	<i>measure</i> : $F(1,11) = 19.77$ , $P < 0.001$ , $\eta^2 < 0.01$ ), an effect that further depended on whether
487	attention or synchrony caused the modulation (interaction gain measure * gain type:
488	F(1,11) = 7.85, P = 0.017, η <sup>2</sup> < 0.01).
489	However, we disregarded these small effects to investigate the gain type * SSR component
490	interaction more closely. First, SSR amplitude and ITC-based modulation indices were tested
491	against zero. Attention systematically modulated all SSR components (see Figures 4E & F;
492	asterisks denote significant deviations from zero at a Holm-Bonferroni corrected alpha level
493	of <i>P</i> < .05). Synchrony, in turn, only modulated pulse 2f, but not pulse 1f and flicker 1f
494	responses for both, SSR power- and ITC- based modulation indices.
495	Given these highly similar patterns we pooled across measures. Then we tested gain
496	differences (Attention minus Synchrony) between SSR components. Elucidating the gain
497	type * SSR component interaction, gains differed more for flicker 1f than for pulse 1f SSRs
498	$(t(11) = 3.03, P_{HB} < .05)$ and for pulse 2f SSRs $(t(11) = 3.06, P_{HB} < .05)$ . In turn, gain differences
499	were statistically comparable between pulse 1f and pulse 2f SSRs (t(11) = $-0.92$ , P = $.376$ )
500	highlighting the exclusive role of the flicker-driven signal component.
501	→ Insert Figure 4 here
502	4. DISCUSSION
503	The role of top-down attention in multisensory binding and, conversely, bottom-up
504	

504 multisensory influences on attentional orienting have been studied largely independent of

505 each other (Talsma et al., 2010). The present study was designed to bridge this gap.

506	Specifically, we studied situations in which participants attended to the position of one of
507	two pulsing and flickering stimuli providing it with a top-down processing advantage over
508	the other stimulus. Additionally, a tone pulsing in synchrony with either the attended or
509	unattended stimulus was introduced to produce a strong multisensory bottom-up bias in
510	visual processing. EEG-recorded SSRs driven by stimulus flicker and pulsation allowed us to
511	test whether and how spatial attention and audio-visual synchrony acted, and possibly
512	interacted, to facilitate cortical visual stimulus processing.
513	
514	We evaluated two commonly used SSR measures, evoked power and inter-trial phase
515	coherence (ITC) to quantify modulations in stimulus processing. Both measures widely agree
516	on patterns of effects and will thus be considered jointly in the following.
517	
518	Briefly summarizing the results, spatial attention facilitated pulse- and flicker-driven SSRs. In
519	contrast, synchrony specifically facilitated pulse-driven SSRs only with greater effects on
520	pulse 2f components while leaving flicker 1f components unaffected. Most importantly,
521	attention and synchrony produced independent additive gain effects. We confirmed that,
522	given our data, an additive model of both influences was more plausible than assuming
523	interactive effects. These findings replicate results from an earlier study using a related
524	paradigm. In that study we tested concurrent influences of feature-based attention and
525	audio-visual synchrony on two spatially super-imposed Gabor patches (Keitel and Müller,
526	2015).
527	Y ·
528	4.1. Spatial attention facilitates processing of all stimulus aspects

528 **4.1. Spatial attention facilitates processing of all stimulus aspects** 

529 The described effects of spatial attention are in line with numerous studies demonstrating
530 sensory gain effects on SSR-indexed cortical visual processing (Müller et al., 1998a; Störmer

531 et al., 2014; Walter et al., 2015). Interestingly, our results show that spatial attention has

532	comparable effects on SSRs driven by two different but simultaneous rhythmic changes in
533	stimulus appearance: a relatively fast on-off flicker (> 14 Hz) and a slow-paced sinusoidal
534	spatial frequency modulation (3 – 4 Hz). These results support the notion that spatial
535	attention prioritizes all aspects of sensory information within its focus (Andersen et al.,
536	2008; Keitel and Müller, 2015) as is central to psychological (Treisman and Gelade, 1980;
537	Wolfe, 1994) and neurophysiological models of attention (Bundesen et al., 2015; Reynolds
538	and Heeger, 2009).
539	Note that participants performed better in the visual detection task when they attended to
540	the left stimulus. This effect could be due to a left-hemifield advantage as has been
541	described previously for rapid serial visual presentation paradigms (Śmigasiewicz et al.,
542	2014; Verleger et al., 2011). In turn, SSR analyses did not show differences in stimulus
543	processing between left and right stimulus positions. It is therefore possible that the
544	imbalance in task performance did not stem from differences in early visual processing of
545	left and right stimuli but was introduced at a later processing stage.
546	
547	4.2. Synchrony selectively facilitates stimulus aspects relevant for multisensory integration

548 Facilitation of visual processing by audio-visual synchrony has largely been studied using 549 transient stimuli (Busse et al., 2005; Talsma et al., 2009). So far, only a few studies have 550 demonstrated synchrony-driven effects while employing dynamic ongoing stimulation 551 (Keitel and Müller, 2015; Nozaradan et al., 2012; Schall et al., 2009). Prolonged exposure to 552 synchronous sensory input, however, can be a vital factor in multisensory integration 553 because it improves the estimate of temporal correlations between visual and auditory 554 stimuli over time (Parise and Ernst, 2016). This is important in situations with multiple 555 concurrent stimuli (as studied here) because even unrelated visual and auditory events can 556 occur simultaneously occasionally.

557

558	Our study corroborates this role of ongoing audio-visual synchrony. Interestingly, synchrony-				
559	related gain effects were thereby restricted to SSR components that reflected stimulus				
560	pulsing, i.e. those rhythmic modulations that produced the impression of synchrony.				
561					
562	Visual stimulus dynamics either matched with or differed from the spectral profile of the				
563	auditory stimulus, thus providing either maximal or minimal temporal correlation. Less				
564	intuitively, the SSR component at twice the pulsation rate (pulse 2f) showed greater				
565	synchrony modulations than the pulse-frequency following response (pulse 1f). In line with				
566	Keitel et al. (2015), who employed a stimulus with similar dynamic properties, the pulse 2f				
567	modulation was accounted for by the transients elicited by the stimulus at twice the				
568	stimulus pulsation rates during maximum up- and down-slopes of the sinusoidal modulation,				
569	or alternatively its extrema, i.e. peaks and troughs.				
570					
571	We propose that successive cross-modal phase resets may be the neural process underlying				

572 synchrony-related modulation of both pulse-driven components. Cross-modal phase 573 resetting has been considered as the primary channel for multisensory interactions between 574 early sensory cortices (Lakatos et al., 2009; van Atteveldt et al., 2014). Unlike neurons in 575 higher order cortices, which are intrinsically multisensory (and hence sensitive to combined 576 multisensory information) neurons in early sensory cortices are primarily sensory specific, 577 but crucially sensitive to temporal information conveyed also by non-specific modalities. As 578 underlined by Lakatos et al. (2008), appropriately timed inputs in one modality can aid in 579 processing a stimulus presented in a different modality. In our case these connections may 580 support phase stability of visual SSRs by providing a cross-modal temporal scaffold (Kayser et 581 al., 2010; Lakatos et al., 2009). As a consequence, the temporal precision of cortical stimulus 582 representations increases, which awards them a processing advantage (Chennu et al., 2009).

583

584	Although our results are broadly in line with Nozaradan et al. (2012), who firstly measured
585	synchrony effects on SSRs, it is worth noting a discrepancy: In contrast to our findings the
586	authors reported an effect on a flicker-driven SSR with a frequency of 10 Hz, while
587	establishing synchrony with auditory beats at either 2.1 or 2.4 Hz. These differences may be
588	accounted for by the fact that the authors presented only one visual stimulus centrally. In
589	this setup, gain effects cannot not unambiguously be ascribed to synchrony, or alternatively,
590	altered attentional demands between synchronous and asynchronous conditions.
591	
592	4.3. Facilitatory effects of spatial attention and synchrony add up
593	We found that attended and unattended stimulus experienced comparable gain through
594	synchrony. Vice versa, synchronous and asynchronous stimuli were similarly facilitated when
595	their position was attended. Remarkably, these findings point towards a dual reign of
596	attention and audio-visual synchrony in early sensory cortices, suggesting that both
597	influences can work independently and in parallel. This result seemingly contradicts previous
598	studies (Alsius et al., 2005; Fairhall and Macaluso, 2009) that showed an interdependence
599	between attention and multisensory interactions. However, this contradiction can be
600	reconciled by examining the experimental paradigm employed in the current study.
601	
602	Unlike previous experiments, in which mutual input from different senses was essential for

502 Solution of the previous experiments, in which induct moutherent senses was essential for 503 successful behavioral performance, it is hard to construe a direct benefit from audio-visual 504 synchrony in performing our task, i.e. the purely visual detection of luminance changes. Our 505 paradigm might thus have promoted the independence between attention and audio-visual 506 interactions triggering two concurrent, but distinct processes: On the one hand, performing 507 the detection task required a sustained goal-driven deployment of spatial attention, while 508 on the other hand merging the audio-visual signals was most likely a stimulus-driven

process, triggered by the high temporal correlation between auditory and visual signalcomponents.

611

011	
612	For these two processes to co-occur independently, we assumed the involvement of distinct
613	neural pathways. Various aspects of attention and its influence on perception have been
614	related to a number of anatomical networks (Shipp, 2004). To date, a dorsal fronto-parietal
615	network, which entails the intra-parietal sulcus (IPS) in posterior parietal cortex, a portion of
616	the precentral supplemental motor area, the so-called frontal eye fields (FEF) and early
617	sensory areas, such as visual cortex has been described most comprehensively (Corbetta and
618	Shulman, 2002). This cortical network has been implicated in the control of attention
619	(Corbetta et al., 1998) and was likely involved in deploying the resources necessary to
620	perform in our behavioral task.
621	
622	On the other side, auditory influences on visual processing could have been conveyed by
623	two candidate routes that have been suggested as a results of earlier invasive
624	electrophysiological and anatomical studies in the animal brain: (1) feed-forward
625	projections between thalamus and early sensory cortices (Cappe et al., 2009), (2) lateral
626	projections between early sensory cortices (Falchier et al., 2002). From our data alone, we
627	cannot say which pathway was critical in the investigated situation. Both neural pathways
628	however are anatomically distinct from the fronto-parietal attention network (as described
629	above) and are thus consistent with our results.
630	

631 It should be mentioned that our data analyses and interpretation of results depend on the

632 implicit assumption that attention and synchrony effects follow similar time courses and,

- once established, remain constant through the course of each trial. At least for, spatial
- 634 attention we know that gain effects reach asymptote after ~500 ms and keep level for

635	several seconds (Müller et al., 1998b). A time course for synchrony-related gain instead has
636	not been established yet. This uncertainty notwithstanding, we restricted our analyses to a
637	period starting 500 ms after stimulus onset. We were confident that this time frame would
638	allow for enough audio-visual coincidence to be detected to establish synchrony. The
639	comparison of temporal profiles of attention- and synchrony related gain remains an
640	interesting subject for future studies, nevertheless.
641	
642	As a final remark, Talsma et al. (2010) suggested that bottom-up multisensory integration
643	benefits a given stimulus the most when competition within one sensory modality is high,
644	e.g. when the visual field is cluttered. Our situation, with one stimulus presented to each
645	hemifield, promoted only minimal competition. Inter-hemispheric competition is introduced
646	relatively late in the visual processing hierarchy (Schwartz et al., 2007). Moreover,
647	attentional resources seem to split more readily between than within visual hemifields
648	(Franconeri et al., 2012; Störmer et al., 2013; Walter et al., 2015). It would thus be
649	interesting to test how synchrony-related gain effects vary with the amount of competition
650	by placing more than one stimulus within visual hemifields.
651	

651

## **652 4.4. Conclusion**

653 We investigated the concurrent effects of spatial attention and audio-visual synchrony on 654 early cortical visual stimulus processing. Our paradigm allowed us to test both influences in 655 isolation as well as their combined effects. We found that attention-related and synchrony-656 related facilitation add up when an audio-visual synchronous stimulus is attended. Further, 657 attention facilitated pulse- and flicker-driven neural responses while synchrony only 658 targeted pulse-driven responses, i.e. those coding for stimulus dynamics that were relevant 659 for multisensory integration. Consequentially, the present results favor an account in which 660 goal-directed sustained spatial attention and stimulus-driven audio-visual synchrony convey

- their influences independently via different neural processes and possibly along different
- 662 neural pathways. At least for situations similar to the one studied here, this finding implies
- that facilitation through synchrony cannot simply be modelled as a sustained attraction of
- 664 spatial attention.
- 665

## 666 Acknowledgments

- 667 Work was supported by the Deutsche Forschungsgemeinschaft (grant no. MU972/21-1).
- 668 Data presented here were recorded at the Institut für Psychologie, Universität Leipzig. The
- authors appreciate the assistance of Renate Zahn in data collection. Experimental
- 670 stimulation was realized using Cogent Graphics developed by John Romaya at the Laboratory
- 671 of Neurobiology at the Wellcome Department of Imaging Neuroscience, University College
- 672 London.
- 673
- 674 **Conflict of interest:** The authors declare that they have no conflict of interest.

## 896 Figure captions

897

898 Figure 1 Stimulation details. (A) On-screen stimulus display comprising central fixation rings 899 and one Gabor patch per lower left and right visual hemifield. All items not to scale. 900 Participants received auditory stimulation via headphones. (B) Schematic trial time course. 901 An instructive position cue allocates attention to the left or right stimulus. Subsequent 902 ongoing Gabor-patch and tone stimulation are represented by grey sinusoids. (C) A common 903 frequency modulation (FM; solid black line) of auditory tone pitch and the spatial frequency 904 of one of the two Gabor patches produces a synchronous pulsing audio-visual percept. 905 Concurrently, the spatial frequency of the other Gabor patch modulates at a slightly 906 different frequency (dashed grey line), thus rendering it asynchronous to the tone. 907 (D) Frame-by-frame visual stimulation for the right Gabor patch. The illustration shows the 908 first 27 frames of each trial. Note the emphasis on the on-off cycles leading to a 17-Hz flicker 909 along the horizontal axis (black boxes = off-frames) and one full cycle of the spatial 910 frequency modulation leading to a 3.14-Hz 'pulsation' along the vertical axis. 911 912 Figure 2 Stimulus-driven steady-state responses (SSRs) – spectra and scalp maps. (A) SSR 913 power extracted from spectral decomposition of trial-averaged EEG waveforms, thus 914 "stimulus-evoked". Scalp maps show topographical distributions of power for the pulse-915 frequency following (pulse 1f), pulse-frequency doubling (pulse 2f) and flicker-frequency 916 following (flicker 1f) SSR components driven by left and right stimuli respectively. White dots 917 in left-most scalp map highlight the uniform sensor cluster used in all data analyses. Spectra 918 below depict condition-averaged individual power spectra (grey lines) and, superimposed in 919 black, the grand-average spectrum. Arrows indicate peaks that correspond to the respective

driving frequencies (in Hz). (B) Same as (A) but for SSR inter-trial phase consistency (ITC)
measured in arbitrary units (au). (C) Power spectra based on averaged spectral
decompositions of single trials for comparison. Note that this approach emphasizes spectral
characteristics of the ongoing EEG, such as the alpha rhythm (see peaks around 10 Hz,
denoted α), over SSRs given our stimulation.

925

926 Figure 3 SSRs by condition. (A) Condition-resolved grand-average power (dB) spectra. Top 927 panel: Spectra split for Attend Left (dark graph) and Attend Right (light graph) conditions. 928 Bottom panel: Spectra split for conditions in which the tone pulsed in synchrony with the left 929 (dark) or right (light) Gabor patch. Shaded areas represent standard error of the mean 930 (SEM). Arrows pointing to peaks indicate the spatial position of the corresponding driving 931 stimulus (L = left, R = right). (B) Same as in (A) but for SSR inter-trial phase coherence (ITC) 932 measured in arbitrary units (au). (C) Zoom-in on power at SSR component frequencies. For 933 each frequency, box plots showcase inter-individual power distributions. Boxes depict 934 interquartile ranges with medians superimposed as strong horizontal lines. Grey dots signify 935 outliers. A common color code applies (also see color key): Hot colors = corresponding visual 936 stimulus attended; Monochrome = visual stimulus unattended; Light colors = visual stimulus 937 in sync with tone; Dark colors = visual stimulus and tone asynchronous. (D) Same as in C but 938 for SSR inter-trial coherence.

939

Figure 4 Quantifying and comparing attention- and synchrony related gain modulation. (A)
SSR power (in dB) for all three SSR components of interest (*pulse 1f, pulse 2f* and *flicker 1f*)
separated by whether the driving visual stimulus was attended (orange) or unattended (red).
Box plots display inter-individual power distributions. Boxes depict respective interquartile
ranges with medians superimposed as strong horizontal lines. (B) Same as in (A) but for SSR
inter-trial phase coherence (ITC) measured in arbitrary units (au). (C) SSR power (in dB) for

946 *pulse 1f, pulse 2f* and *flicker 1f* components separated by whether the driving visual stimulus

- 947 pulsed in sync with the tone (light grey) or asynchronous (dark grey). (D) Same as in (C) but
- 948 for SSR inter-trial phase coherence (ITC) measured in arbitrary units (au). (E) Boxes indicate
- 949 SSR power modulation (in au) by attention (brown) and synchrony (blue) for *pulse 1f*,
- 950 *pulse 2f* and *flicker 1f* components of interest. (F) Same as in (C) but for modulation of SSR
- 951 inter-trial phase coherence (in au). Grey dots in plots signify outlier values. Asterisks close to
- medians in E & F demarcate statistically significant deviations from zero, i.e. systemic gain
   modulations (two-tailed t-tests, P < .05, Holm-Bonferroni corrected for multiple</li>
- 955 modulations (two-tailed t-tests, P < .05, Holm-Bomerrom corrected for multip 954 comparisons).
