Abstract (100 to 200 words)

While the positive effects of exercise on frailty are well documented, the effect of exercise on quality of life (QoL) and activities of daily living (ADL) in frail older adults remains less certain. Therefore, this paper aimed to systematically review the literature investigating the effect of exercise on QoL and ADL in this group. Embase, MEDLINE, CENTRAL, PEDro and Web of Science Core Collections were searched systematically using relevant MeSH terms. The inclusion criteria were: controlled trial design, published in English, population included frail older adults, frailty measured quantitatively, interventions that included exercise, and QoL or ADL measurements (PROSPERO: CRD42018106173). After screening, 15 studies were eligible for inclusion in the qualitative synthesis (total n: 2,467; mean age range: 70 - 85 years). There was a positive effect on QoL or ADL measures in 10 out of the 15 studies. QoL and ADLs only improved in studies that also reported improved physical outcomes. These results reflect the multi-factoral nature of frailty and how physical capability and QoL are interlinked. Heterogeneity precluded formal meta-analysis. Future trials in frail older adults should focus on interventions that include exercise, measure physical outcomes and use consistent study design to enable meta-analysis to be conducted.

Keywords: Frailty; Ageing; Quality of life; Activities of daily living.

Highlights
- Exercise interventions for frail older adults rarely focus on QoL and ADLs
- There was no obvious link between type of exercise and improvements in QoL and ADLs
- Improvements in QoL and ADLs were only seen with improvements in physical outcomes
- Future clinical trials are still needed to conduct a proper meta-analysis.
1. Introduction

Frailty is a clinical state which primarily affects older adults, places the individual at a high risk of hospital admission and warrants clinical intervention (Fried et al., 2001). Frailty also has negative outcomes on hospitalisation, independence and thus can place a burden on public health care systems. In the United Kingdom, approximately 6.5% of community dwelling older adults aged between 60-69 years are frail, and the prevalence rises tenfold with age to approximately 65% of older adults aged 90 years or more being frail (Gale et al., 2015). Furthermore, the proportion of those living with severe or moderate frailty in the UK is 3 and 12%, respectively (BMA, 2020).

The clinical phenotype of frailty comprises both psychological and physical components evaluating mood, physical condition and physical function (Fried et al., 2001). Frailty has a negative impact on activities of daily living (ADL) and instrumental ADL (IADL) with approximately 60% of those with frailty being negatively impacted compared to approximately 14% of non-frail older adults (Gale et al., 2015). A systematic review and meta-analysis demonstrated an inverse association between quality of life (QoL) and frailty among community-dwelling older people (Kojima et al., 2016). The same review proposed that health interventions aimed at reducing frailty may also have a positive impact on QoL (Kojima et al., 2016). Therefore, ADL and QoL have an important impact in older adults and in geriatric medicine.

Fried et al. defined frailty as a clinical phenotype in 2001 and at the time noted the negative impact that frailty has on QoL (Fried et al., 2001). Since its inception as a clinical phenotype, there have been numerous operational classification tools for frailty (Bouillon et al., 2013). However, it has been shown that not all measurements of frailty are appropriate for all purposes (Martin and Brighton, 2008). A common theme among definitions is a quantitative decrease in physical function or independence (Dent et al., 2016; Devereux et al., 2019), making exercise a potentially effective therapy.

Supervised exercise is safe in frail older adults (de Labra et al., 2015) and is recommended as a possible therapy to reverse frailty and increase independence (Aguirre and Villareal, 2015). A previous systematic review, conducted by Chou et al., assessed the effect of exercise training on ADL and QoL in frail older adults (Chou et al., 2012). The main finding of that systematic review was that there was no effect of exercise on QoL with a small positive effect on ADL observed; however, the results were far from conclusive due to the poor quality and low volume of the evidence (Chou et al., 2012). In addition, the literature search of that systematic review was undertaken in 2010, and since then, there has been a considerable amount of primary research concerning exercise and frailty published. Therefore, another review of the literature is warranted. The current paper aims to
systematically review the literature investigating the effect of exercise on QoL and ADL in older adults who were clinically frail. Furthermore, we wanted to explore if different types of exercise had different effects on QoL in frail older adults and if there were any patterns in the evidence between changes in physical outcomes and changes in ADLs or QoL.

2. Methods

This systematic review was conducted according to the Preferred Reporting Items for Systematic Review and Meta-Analyses (PRISMA) guidelines (Moher et al., 2009). The protocol for this systematic review was published in PROSPERO (ID protocol: CRD42018106173).

2.1. Data sources and search strategy

A systematic search was undertaken in August 2018 using the following databases: MEDLINE, EMBASE, CENTRAL and Web of Science Core collections. Relevant MeSH terms and Boolean phases were used for the search: frail$ AND exercis$ OR train$ OR strength$ without time restriction. QoL and ADL were not included in the initial search strategy as these are often measured as secondary outcomes and therefore, may be not present in abstracts or titles. The complete search strategy is shown in the appendix.

2.2. Study selection

Randomised controlled trials (RCT) or non-randomised clinical trials conducted in frail older people (defined clinically or quantitatively, e.g. using the Fried phenotype (Fried et al., 2001), frailty index or a defined decrement in an ADL measure) with a control group and published in English were considered for eligibility. Study populations could be community dwelling or nursing home residents. Non-human studies, studies including participants younger than 65-years-old or being described as frail with no quantitative measurement of frailty, e.g. all hip replacement patients, and studies without a control group were excluded.

2.3. Data extraction

All articles were screened for suitability by title and abstract by two reviewers (EC and FP-R). If there was insufficient information to gauge eligibility, the methods were screened. Full articles were screened by the same researchers (EC and FP-R). If information was missing or there was ambiguity, the lead author was contacted for clarification. Data from eligible articles were extracted using a standardised form. The form included: authors, date of publication, study design, sample size (intervention and control group), age of participants, was the sample statistically powered, was analysis carried out on the basis of intention to treat, attrition rate, length of intervention, length of
follow-up, frailty measure, type of intervention, frequency and type of exercise, ADL/QoL measure,
other relevant outcomes measures and results.

2.4. Methodological quality assessment

Studies included in the systematic review were further assessed using the PEDro scale. This
instrument evaluates both internal and external validity, gives a score out of 10 and is a reliable scale
of the methodological quality of randomised control trials (de Morton, 2009). Each article was
scored independently by two reviewers (EC and FP-R), and divergent scores were settled by
discussion. Quality assessment was based on the content of the study in the published article. Due
to the nature of frailty exercise studies often using non-frail participants as controls, this removed
the possibility of randomisation from these studies. Due to this, there was no lower limit placed on
PEDro scores.

2.5. Research questions

The primary research question was:

*Does exercise have an effect on QoL or ADL in frail older adults?*

The secondary research question was:

*Does the type of exercise intervention, or the measure of frailty, impact the effect of exercise on QoL
or ADL measures in frail older adults?*
3. Results

3.1. Search results

From the search, 6,395 records were identified. After the removal of 152 duplicates, 6,243 titles and abstracts were screened, 5,695 of which were excluded (Fig. 1). Full texts of 548 studies were read for further information, and further 531 were excluded (Fig. 1). Fifteen studies, described by 17 articles, were included in the qualitative synthesis. In the evidence synthesis, only the primary articles are cited unless describing results specifically from the secondary article. Due to the variation in outcome measures and interventions prescribed, a meta-analysis was not appropriate.

3.2. Quality of studies

PEDro scale scores ranged from three (Rydwik et al., 2010) to eight points (El-Khoury et al., 2015; Fairhall et al., 2012; Helbostad et al., 2004; Hoogeboom et al., 2010; Latham et al., 2003; Littbrand et al., 2009; Talley et al., 2017; Villareal et al., 2006) (Table 1). Scores were most commonly low due to lack of blinding of the participants and therapists delivering the intervention, which is unavoidable in exercise trials (Campbell et al., 2016; Campbell et al., 2018). Studies were not excluded due to a low PEDro score.

3.3. Study characteristics

All studies included were RCTs, no eligible non randomised controlled trials were indentified. The total number of participants from the studies included in the review was 2,467, and the mean age ranged from 70 to 85 years (Table 2) (Cameron et al., 2013; El-Khoury et al., 2015; Giné-Garriga et al., 2010; Grönstedt et al., 2013; Helbostad et al., 2004; Hoogeboom et al., 2010; Latham et al., 2003; Littbrand et al., 2009; Talley et al., 2017; Villareal et al., 2016; Villareal et al., 2017; Villareal et al., 2006; Villareal et al., 2011). Sample size ranged from 21 (Hoogeboom et al., 2010) to 706 participants (El-Khoury et al., 2015). Nine studies provided a sample size calculation (Cameron et al., 2013; El-Khoury et al., 2015; Grönstedt et al., 2013; Helbostad et al., 2004; Latham et al., 2003; Tarazona-Santabalbina et al., 2016; Villareal et al., 2017; Villareal et al., 2006; Villareal et al., 2011) but only two of these calculations were powered for a QoL or ADL outcome (Grönstedt et al., 2013; Latham et al., 2003). Six studies used a clinically validated measure of frailty (Cameron et al., 2013; Hoogeboom et al., 2010; Latham et al., 2003; Littbrand et al., 2009; Rydwik et al., 2010; Tarazona-Santabalbina et al., 2016).
Eight studies included an intervention that was solely exercise (El-Khoury et al., 2015; Giné-Garriga et al., 2010; Helbostad et al., 2004; Hoogeboom et al., 2010; Langlois et al., 2013; Latham et al., 2003; Littbrand et al., 2009; Tarazona-Santabalbina et al., 2016), five studies had a multi-modal intervention which included an exercise component (Cameron et al., 2013; Grönstedt et al., 2013; Talley et al., 2017; Villareal et al., 2017; Villareal et al., 2006), while two studies were multi-armed RCTs which included an interventional arm which was exercise only and another which was multi-modal (Rydwik et al., 2010; Villareal et al., 2011). Other components in multi-modal interventions included a dietary or nutrition intervention (n=5); physical, cognitive or social goal-setting (n=2); physiotherapy (n=1); geriatrician input (n=1); rehabilitation physician input (n=1); and bladder rehabilitation (n=1) (Table 1).

All exercise interventions, bar one (Latham et al., 2003), were multi-component exercise interventions. All studies included strength training in their intervention, 11 included balance training (Cameron et al., 2013; El-Khoury et al., 2015; Giné-Garriga et al., 2010; Grönstedt et al., 2013; Helbostad et al., 2004; Langlois et al., 2013; Littbrand et al., 2009; Rydwik et al., 2010; Tarazona-Santabalbina et al., 2016; Villareal et al., 2006; Villareal et al., 2011), nine included aerobic training (Cameron et al., 2013; Grönstedt et al., 2013; Hoogeboom et al., 2010; Langlois et al., 2013; Rydwik et al., 2010; Tarazona-Santabalbina et al., 2016; Villareal et al., 2017; Villareal et al., 2006; Villareal et al., 2011), four included flexibility exercises (El-Khoury et al., 2015; Tarazona-Santabalbina et al., 2016; Villareal et al., 2011), four included functional exercises (Cameron et al., 2013; Hoogeboom et al., 2010; Littbrand et al., 2009; Rydwik et al., 2010), and two included walking (Grönstedt et al., 2013; Littbrand et al., 2009). Thirteen of the exercise interventions were supervised (El-Khoury et al., 2015; Giné-Garriga et al., 2010; Grönstedt et al., 2013; Helbostad et al., 2004; Hoogeboom et al., 2010; Langlois et al., 2013; Littbrand et al., 2009; Rydwik et al., 2010; Talley et al., 2017; Tarazona-Santabalbina et al., 2016; Villareal et al., 2017; Villareal et al., 2006; Villareal et al., 2011) while two were unsupervised home exercise plans (Cameron et al., 2013; Latham et al., 2003).

The lowest frequency of training was twice a week (Giné-Garriga et al., 2010; Helbostad et al., 2004; Hoogeboom et al., 2010; Rydwik et al., 2010) and the highest five times a week (Cameron et al., 2013; Talley et al., 2017; Tarazona-Santabalbina et al., 2016). Nine studies reported intensity of the exercise prescribed which was typically between 60-80% of maximal capability (Giné-Garriga et al., 2010; Helbostad et al., 2004; Hoogeboom et al., 2010; Latham et al., 2003; Littbrand et al., 2009; Rydwik et al., 2010; Tarazona-Santabalbina et al., 2016; Villareal et al., 2017; Villareal et al., 2011). Seven of those progressed the intensity of exercises to keep them challenging (Giné-Garriga et al., 2010; Helbostad et al., 2004; Hoogeboom et al., 2010; Latham et al., 2003; Littbrand et al., 2009; Rydwik et al., 2010; Tarazona-Santabalbina et al., 2016; Villareal et al., 2017; Villareal et al., 2011).
2010; Hoogeboom et al., 2010; Latham et al., 2003; Littbrand et al., 2009; Tarazona-Santabalbina et al., 2016; Villareal et al., 2017; Villareal et al., 2011), one did not progress the exercise (Talley et al., 2017) and one did not report if there was progression (Rydwik et al., 2010). Six studies did not report the intensity of their exercise intervention (Cameron et al., 2013; El-Khoury et al., 2015; Grönstedt et al., 2013; Helbostad et al., 2004; Langlois et al., 2013; Villareal et al., 2006), but two of these did report that they progressed exercises so that they remained challenging (Cameron et al., 2013; Grönstedt et al., 2013). Trial intervention length ranged from three weeks (Hoogeboom et al., 2010) to two years (El-Khoury et al., 2015); however, the most common length of the intervention was 12 weeks which was employed in seven studies (Giné-Garriga et al., 2010; Grönstedt et al., 2013; Helbostad et al., 2004; Langlois et al., 2013; Littbrand et al., 2009; Rydwik et al., 2010; Talley et al., 2017).

Thirteen different QoL and ADL outcome measures and 37 other outcome measures of varying domains were used across the 15 studies (Table 2).

3.4. Primary research question: Does exercise have an effect on QoL or ADL in frail older adults?

The superiority of the exercise intervention over control for QoL or ADL, was reported in nine studies (El-Khoury et al., 2015; Giné-Garriga et al., 2010; Helbostad et al., 2004; Langlois et al., 2013; Tarazona-Santabalbina et al., 2016; Villareal et al., 2017; Villareal et al., 2011) (Grönstedt et al., 2013; Villareal et al., 2006) with varying effect sizes for QoL and ADL (Table A-1). From these nine studies, between-group improvements in the exercise group, or maintenance in the exercise group and with deterioration in the control group, in QoL or ADL measures, were reported in seven studies (El-Khoury et al., 2015; Giné-Garriga et al., 2010; Helbostad et al., 2004; Langlois et al., 2013; Tarazona-Santabalbina et al., 2016; Villareal et al., 2017; Villareal et al., 2011). In two studies, there were within-group improvements in the exercise group (Grönstedt et al., 2013; Villareal et al., 2006). In one study, there were improvements seen in both the intervention and control groups (Talley et al., 2017) with no overall superiority in the exercise group. However, in five studies, there was no effect on QoL or ADL in either the exercise group or control groups (Cameron et al., 2013; Hoogeboom et al., 2010; Latham et al., 2003; Littbrand et al., 2009; Rydwik et al., 2010). In summary, there was a positive effect on QoL or ADL measures in 10 out of the 15 studies included in the review. It is, therefore, unclear if exercise had an effect on QoL or ADL in frail older adults.
3.5. Secondary research question: Does the type of exercise intervention, or the measure of frailty, impact the effect of exercise on QoL or ADL measures in frail older adults?

Of the nine studies which observed improvement or maintenance from the exercise intervention on QoL or ADL measures, four used a clinically validated measure of frailty (Langlois et al., 2013; Tarazona-Santabalbina et al., 2016; Villareal et al., 2017; Villareal et al., 2006) and five did not (El-Khoury et al., 2015; Giné-Garriga et al., 2010; Grönstedt et al., 2013; Helbostad et al., 2004; Villareal et al., 2011) (Table 2). Similarly, in the six studies which did not observe an improvement, four employed a clinically recognised frailty measure (Cameron et al., 2013; Hoogeboom et al., 2010; Latham et al., 2003; Rydwik et al., 2010) while two did not (Littbrand et al., 2009; Talley et al., 2017).

From the studies included in this review, there was no evidence to suggests that using a clinically recognised measure of frailty impacted on the effect of exercise on QoL or ADLs.

All exercise interventions bar one (Latham et al., 2003), were multi-component exercise interventions and all studies included strength training. Due to the large variation in exercise interventions implemented (Table A.1) and the heterogeneity of the results, it is unclear if the type of exercise used would have different effects on QoL and ADL measures in frail older adults.

Of the nine studies where improvements were reported, six utilised an exercise-only intervention (El-Khoury et al., 2015; Giné-Garriga et al., 2010; Helbostad et al., 2004; Langlois et al., 2013; Tarazona-Santabalbina et al., 2016; Villareal et al., 2011) and three were part of a multi-modal intervention (Grönstedt et al., 2013; Villareal et al., 2017; Villareal et al., 2006). The other components in the multi-modal interventions included a dietary intervention (Villareal et al., 2017; Villareal et al., 2006) and goal setting (Grönstedt et al., 2013). Similarly, of the trials in which no positive effects of exercise were observed, four were exercise-only interventions (Hoogeboom et al., 2010; Latham et al., 2003; Littbrand et al., 2009; Rydwik et al., 2010) and two were part of multi-modal interventions (Cameron et al., 2013; Talley et al., 2017). The other components of the multi-modal interventions were bladder rehabilitation (Talley et al., 2017) and a multi-disciplinary intervention including input from a physiotherapist, dietician, geriatrician, a rehabilitation specialist, and goal setting (Cameron et al., 2013). In summary, there was no evidence to suggest that the effectiveness of exercise depended on whether it was prescribed as part of a multi-modal intervention or by itself on QoL or ADL measures in frail older adults.

All nine studies which observed a positive effect of exercise on QoL or ADL also observed an improvement in physical outcome measures (El-Khoury et al., 2015; Giné-Garriga et al., 2010; Grönstedt et al., 2013; Helbostad et al., 2004; Langlois et al., 2013; Tarazona-Santabalbina et al., 2016; Villareal et al., 2017; Villareal et al., 2006; Villareal et al., 2011). Of the six studies that did not
observe a positive effect of exercise on ADL or QoL measures, four reported an improvement in physical outcome measures (Cameron et al., 2013; Littbrand et al., 2009; Rydwik et al., 2010; Talley et al., 2017) and two did not (Hoogeboom et al., 2010; Latham et al., 2003). From the studies included in the review, it would appear that improvements in physical function do not necessarily result in improvements in ADL and QoL, but when these are increased, physical function is also increased.
4. Discussion

4.1. Main findings

This systematic review identified 15 RCTs that examined the effect of exercise on QoL or ADLs in frail older adults. Overall, the published studies produced inconsistent findings on whether prescribed exercise led to a positive effect on QoL or ADLs in frail older adults. This lack of consistency is likely to reflect heterogeneity in study design and the interventions evaluated. Interestingly QoL and ADLs only improved in studies that also reported improved physical outcomes. There was no evidence that using a clinically validated measure of frailty impacted the results.

4.2. Comparison with previous studies

The findings of this review are broadly in line with the previous systematic review and meta-analysis which also concluded that there was no noticeable effect of exercise on QoL (Chou et al., 2012). Chou et al. did observe, in their meta-analysis, an improvement in ADLs after exercise training (Chou et al., 2012); however, this result was based on three trials with heterogeneity in the intervention prescribed and outcomes measured. Likewise, in this present review, large heterogeneity was observed in the interventions prescribed and the outcome measures used. For these reasons, a meta-analysis of the results would have been inappropriate (Higgins et al., 2019). The authors of a systematic review, published in 2011, examining the effect of exercise on the management of frailty also chose not to conduct a meta-analysis of their results when examining the effect of exercise on QoL or ADLs in frail older adults (Theou et al., 2011). These authors also concluded that it was not possible from the included literature to determine an effect or not. Subsequently, it is recommended that future trials for frail older adults should be more consistent in regard to intervention prescription and outcome measures used. Such homogeneity with a primary focus on ADLs and QoL would allow a robust meta-analysis to draw a firm conclusion.

4.3. Implications of the findings

Frailty is theoretically defined as a clinically recognisable state of increased vulnerability resulting from an ageing-associated decline in reserve and function across multiple physiologic systems, such that the ability to cope with everyday or acute stressors is comprised. Since Fried defined the clinical phenotype in 2001 (Fried et al., 2001), there has been a plethora of frailty measures and indices created (Walston et al., 2018). Indeed, in the review by Chou et al., the authors created their own definition of frailty based on the Fried criteria and used this definition as an inclusion criterion (Chou et al., 2012). Given the large number of frailty measures available, research is needed to compare these recognised measures and ‘ad hoc’ quantitative measures to investigate if using a recognised
measure is in fact necessary or if simply measuring a decrease in physical and psychological function is sufficiently sensitive to identify frail older adults.

To our knowledge, this is the first review to date to question whether using a recognised measure of frailty impacts upon findings around the effect of exercise. There was no evidence of a difference in whether there was a positive effect, or not, of exercise on QoL or ADLs in studies which included a clinically recognised measure or frailty or not. Additionally, there was some evidence that improvements in QoL and ADLs may be linked to improvements in physical outcomes. In this systematic review, it was observed that there was a positive effect on QoL or ADLs in all of the studies that also reported an improvement in a physical outcome measure (e.g. balance) and none of the studies that did not. This is logical if we consider that frailty is, by definition, multifactorial (Fried et al., 2001); therefore, addressing the physical aspects of frailty will have an impact on QoL and ADLs aspect. This may indicate that the improvements in physical function do not necessarily result in improvements in ADL and QoL, but when these are increased, physical function is increased as well. This is a novel finding when it is compared to previous reviews (Chou et al., 2012; Theou et al., 2011) and with an umbrella review of systematic reviews which found that exercise seemed to have a positive effect on QoL frail older adults; however, the optimum exercise program remained still unclear (de Labra et al., 2015). Consequently, this theory could be tested robustly if there is greater homogeneity in interventions, outcome measures and an optimum exercise programme is identified. A hypothetical pathway of the influence of exercise on physical function, frailty and QoL and ADLs can be seen in figure A.1.

4.4. Strengths and limitations

This work was conducted in accordance with the recommendations from the PRISMA statement (Moher et al., 2009). Study selection, data extraction and assessment of quality were carried out by two independent reviewers (Higgins et al., 2019). However, one of the main limitations of this study was the inclusion of articles in English only. This could have limited the involvement of other frailty populations from other regions (e.g., China and Latin America) and generated a language bias. In addition, the heterogeneity of the studies in terms of intervention and study methodology prohibited the derivation of pooled estimates from a meta-analysis. Such limitations are commonplace in interventions which have such large possible variations such as exercise regimes. As with all qualitative syntheses, any comparisons made are observational, and causality cannot be inferred. Finally, the literature search was carried out two years ago and may not reflect the most recent literature. However, the last set of authors to review this topic carried out their literature
search more than 10 years ago, therefore this present document still makes a valid contribution to
the literature.

4.5. Conclusions

In conclusion, heterogeneity in study design and the intervention evaluated has produced
inconsistent findings, to date, as to whether prescribed exercise improves QoL or ADLs in the frail
elderly. However, further scrutiny suggests that, to be effective in QoL or ADLs, exercise
interventions may have generated a positive effect on physical outcomes too. Future trials should
use a consistent methodology and focus on this type of intervention so that robust conclusions can
be drawn.

*Cameron et al. (Cameron et al., 2013) and Fairhall et al. (Fairhall et al., 2012) describe the same study. Only Cameron et al. is described here because it had a higher PEDro score.

+Villareal et al. (Villareal et al., 2011) and Napoli et al. (Napoli et al., 2014) describe the same study. Only Villareal et al. is described here because it had the higher PEDro score.

1: Eligibility criteria were specified (no point awarded for this criterion), 2: Subjects were randomly allocated to groups, 3: Allocation was concealed, 4: Groups were similar at baseline regarding the most important prognostic indicators, 5: There was blinding of all subjects, 6: There was blinding of all therapists who administered the therapy, 7: There was blinding of all assessors who measured at least one key outcome, 8: Measures of at least one key outcome were obtained from more than 85% of the subjects initially allocated to groups, 9: All subjects for whom outcome measures were available received the treatment or control condition as allocated or, where this was not the case. Data for at least one key outcome was analysed by "intention to treat", 10: The results of between-group statistical comparison are reported for at least one key outcome, 11: The study provides both point measures and measures of variability for at least one key outcome.
