Abstract—In this research, we presented an electromagnetically induced transparency-like (EIT-like) metasurface. The structure is composed of pairs of L-shaped resonators, and by increasing the asymmetry between the coupled resonators, the dark mode has been excited with a transparency peak at 2.84 THz. The transmission spectra based on various asymmetry degree shows the intensifying trend of EIT-like resonance. The distribution of the electromagnetic field and the surface current were also examined to demonstrate the dark mode excitation. The sensing performance of the biosensor was studied based on various refractive index and thicknesses of the sample, and a total theoretical sensitivity of 800 GHz/RIU based on a narrow line width of 230 GHz was achieved. The results also were compared with similar research works and proved a massive enhancement in sensitivity and Q-factor. The proposed structure can be served as an ultra-sensitive, inexpensive, and label-free biosensor for applications including biological sensing.

Index Terms—THz Metasurface, Biosensor, Electromagnetically Induced Transparency.

I. INTRODUCTION

Terahertz (THz) radiation has been widely adopted for biosensing applications due to its non-ionizing nature and non-label and high-resolution characteristics. This enables the possibility of acquiring spectral measurements without perturbation of the biological sample. Metasurfaces are two-dimensional versions of metamaterials, defined as artificial structures whose size scale is significantly smaller than the wavelength of the incident electromagnetic wave. In THz metasurfaces, light-matter interaction is enhanced due to the excitation of higher-order surface plasmon-like modes. This, in turn, provides excellent field confinement, which boosts the interaction between the metasurface sensor and the biological sample, thus increasing its sensitivity. Classical plasmonic metamaterial sensors rely on split ring resonators manufactured on a dielectric/semiconductor substrate.

Various metasurface types exhibit higher-order plasmonic resonances utilized for thin film sensing. Nanoparticle-enhanced metasurfaces can enhance strong fields by triggering the localized surface plasmons [1]. THz metasurfaces based on graphene also has been widely used for biosensors. When the analyte is present, it shifts the fermi energy level of the graphene, giving a shift in the electromagnetic response due to the change in conductivity compared to the empty structure [2]. Another alternative would be devices based on nano-hole arrays in which subwavelength hole dimensions in a metallic material achieve what is known as extraordinary transmission at specific frequencies. The presence of analyte shifts the transmission frequency giving rise to detection capabilities compared to the empty structure [3].

In order to have a sharp resonance and high sensitivity in a biosensor system, we need to design high-Q factor structures. Exciting dark mode and higher order plasmonic electromagnetically induced transparency (EIT-like) resonance in the metasurfaces suppresses more radiation losses of the system and leads to forming a transparency window with a narrow line width. This phenomenon raises the interaction of the
The proposed terahertz metasurface design includes two pairs of L-shape resonators. Their dimensions can be seen in Fig. 1. A 200nm gold layer was used for the L-shape resonators. A 5µm polyimide was used with a dielectric constant of 2.9 and tangent delta of 0.02. Parametric analysis was performed on the metasurface structure to determine the best dual L-shape pairs configuration. Parameter α was defined as the vertical downward translation of the right L-shape resonator of the left pair. This parameter has been used to make an asymmetry in the design in order to excite an EIT-like resonance. The incident THz waves transfer from the metal where the sample was placed to the dielectric layer. The dimensions of the unit cell geometries is mentioned in the caption of Fig. 1. The metasurface unit cell is simulated and optimized by the CST microwave studio based on a finite difference time domain (FDTD) solver. The electric, magnetic and open (add space) boundary conditions are considered along x, y, and z directions, respectively.

III. RESULTS AND DISCUSSION

The simulated transmission spectra of the structure with different asymmetry degrees of α are presented in Fig. 2.

The coupling of the bright and dark modes causes the transparency windows to peak at 2.84 THz at α equal to 8 µm. As can be seen, the coupling strength between the resonators gradually increases as the degree of asymmetry α grows from 0 to 8 µm. As a result, the transparency window intensifies and becomes increasingly obvious as the degree of asymmetry increases.

In Fig. 3, the structure’s magnetic field and current distribution is shown at the transparency peak frequency of f2 and the two resonance dips of f1 and f3. It shows that at f1, a weak magnetic field is produced on each side of the resonator pairs due to an incomplete semi-circulating current. Then a magnetic dipole, as well as a complete circulating current, is produced between the resonators at frequency f2, causing destructive interference and a suppressed condition in the bright resonator. As a result, a transparency window was created at this frequency, and radiative losses were reduced and the structure’s EIT-like Fano resonance relies entirely on non-radiative dampings, such as the loss of the metal components. Due to the fact that any change in the lineshape deviation can only be explained by a change in the external
dielectric environment, this exceptional feature encourages the development of ultra-sensing behavior [20]. At the frequency of $f_3$, the transmission transparency disappeared, and radiation losses took over. This resulted in the reformation of a weaker out-of-phase current distribution [7].

The theoretical sensitivity based on refractive index variations has been calculated to study the suggested metasurface’s sensing capabilities further. The ratio of the frequency shift of the pick frequency to the change in refractive index determines theoretical sensitivity. We simulated an analyte with a thin thickness of 15 µm and altered its refractive index from 1 to 1.6, which corresponds to the permittivity range of skin [12], to demonstrate the bio-sensing capacity of the suggested structure. Fig. 4 illustrates the linear shift in the transmission spectra’s peak toward the lower range. The transmission peak frequency varies from 2.84 THz to 2.36 THz with a refractive index change from 1 to 1.6, resulting in a characteristic theoretical sensitivity ($S = \Delta f / \Delta n$) of 800 GHz/RIU (RIU is the unit of refractive index). Moreover, we have analyzed the sensitivity of the biosensor to the sample thickness. Therefore, we simulated the sample with a fixed refractive index of 1.6 and varied the thickness from 1 to 15 µm. It can be seen in Fig. 5 that increasing the thickness makes the EIT-like resonance shift to a lower frequency. It can be observed that this change gets smaller after 9 µm and nearly unchanged after 15 µm. The concentrated electromagnetic fields restricted to the surface area cause this saturation.

The FWHM of the resonance response is calculated to be as narrow as 230 GHz using the Fano resonance and the special design. The comparison of these results with other THz biosensors operating in the frequency range of 1-3 THz (compatible with the THz-TDS system) is presented in Table 1. It comprises $n_a$ and $h_a$, which stand for the sample’s refractive index and thickness, respectively.
index and thickness, $f_0$, which stands for the metamaterial’s resonance frequency in the absence of an analyte, as well as FWHM of the corresponding bare biosensor. As can be observed, there has been a notable improvement in theoretical sensitivity in this work. Additionally, the FWHM is smaller and helps to suppress more losses and get a sharp sensitivity. Based on the discussion, the proposed structure can be utilized in thin film biological sensing.

ACKNOWLEDGMENT

This research was supported by the James Watt School of Engineering, University of Glasgow.

IV. CONCLUSION

A metasurface based on the excitation of dark mode and EIT-like resonance is proposed in this work. It proved that when the bright and dark resonators are coupled, a transparency window at 2.84 THz is created, non-radiation damping is reduced, and any fluctuation in the transparency lineshape spectra is attributable to the variation in the surrounding dielectric environment. A parametric investigation of the coupling strength of the resonators was conducted, along with the electromagnetic fields and surface current distribution of the resonators that were developed using an EIT-like system. Additionally, the system’s sensitivity performance was confirmed by various refractive index and thicknesses of the sample, and a total theoretical sensitivity of 800 GHz with a narrow FWHM of 230 GHz was achieved. These results were compared with other works, and a significant enhancement in sensitivity parameters was observed.
