Abstract

Grapheme-colour synaesthetes experience an anomalous form of perception in which graphemes systematically induce specific colour concurrents in their mind’s eye (“associator” type). Although grapheme-colour synaesthesia has been well characterised behaviourally, its neural mechanisms remain largely unresolved. There are currently several competing models, which can primarily be distinguished according to the anatomical and temporal predictions of synaesthesia-inducing neural activity. The first main model (Cross-Activation/ Cascaded Cross-Tuning and its variants) posits early recruitment of occipital colour areas in the initial feed-forward sweep of brain activity. The second (Disinhibited Feedback) posits: (i) later involvement of a multisensory convergence zone (for example, in parietal cortices) after graphemes have been processed in their entirety; and (ii) subsequent feedback to early visual areas (i.e., occipital colour areas). In this study, we examine both the timing and anatomical correlates of associator grapheme-colour synaesthetes (n=6) using MEG. Using innovative and unbiased analysis methods with little a priori assumptions, we applied Independent Component Analysis (ICA) on a single-subject level to identify the dominant patterns of activity corresponding to the induced, synaesthetic percept. We observed evoked activity that significantly dissociates between synaesthesia-inducing and non-inducing graphemes at approximately 190 ms following grapheme presentation. This effect is present in grapheme-colour
synaesthetes, but not in matched controls, and exhibits an occipito-parietal topology localised consistently within individuals to extrastriate visual cortices and superior parietal lobes. Due to the observed timing of this evoked activity and its localisation, our results support a model predicting relatively late synaesthesia-inducing activity, more akin to the Disinhibited Feedback model.

Keywords: synaesthesia, MEG, ICA, occipito-parietal cortex, multisensory

1. Introduction

In synaesthesia, stimulation of one sensory modality triggers a perceptual or cognitive experience in another sensory modality. One of the most prominent and best-studied forms of synaesthesia is grapheme-colour synaesthesia, in which graphemes elicit specific colour percepts either in external space (termed “projector” synaesthesia) or in the mind’s eye (“associator” synaesthesia). These additional colour experiences are elicited automatically, involuntarily, and systematically in response to specific graphemes (i.e., in unique grapheme-colour pairs). Despite the perceptual reality of these induced percepts, they are not generally confused with components of the external world. This suggests that induced synaesthetic colours are not equivalent to real colour perception and may thus involve a distinct network of brain areas other than those implicated in real colour perception.

The neural correlates of grapheme-colour synaesthesia remain largely unresolved. There are several proposed models describing its underlying neural mechanisms (Lalwani & Brang, 2019; Hubbard, Brang, & Ramachandran, 2011). These models (e.g., Disinhibited Feedback, Cross-Activation, Two-Stage, Stochastic Resonance) primarily diverge on the predicted brain areas involved and the timing of induced synaesthetic activity. Many studies exploring different aspects of the synaesthetic experience using fMRI have enlightened our understanding of its anatomical underpinnings, but overall have yielded conflicting and often ambiguous results. The brain areas commonly reported as supporting the synaesthetic experience
(i.e., not only the induced percept but also other associated aspects) include ventral-occipital, parietal, insular and precentral regions of both the left and right hemispheres (see Rouw, Scholte, and Colizoli (2011) for a review). The inconsistency in these reported findings has been largely attributed to statistical and methodological caveats but also to the heterogeneity in the synaesthetic phenomenology exhibited between individuals (see Hupe, Bordier, & Dojat, 2012 and Hupe & Dojat, 2015 for a review and insights regarding this matter). van Praag and colleagues (2016) demonstrated that activity in colour-specific brain areas (which were individually defined and also varied between individuals) varied among synaesthetes and was correlated with synaesthetic phenomenology. Based on their findings, they propose that the seemingly contradictory findings reported over the past two decades may at least partially reflect the heterogeneity between synaesthetic individuals, emphasising the need for methodological approaches that can account for individual differences in the synaesthetic concurrent.

Few studies have directly investigated the timing of the induced synaesthetic percept using methodological approaches with more precise temporal resolution than fMRI, like electro- or magnetoencephalography (M/EEG) (Teichmann et al., 2021; Brang, Hubbard, Coulson, Huang, & Ramachandran, 2010). Some studies have explored other aspects of synaesthesia, such as semantic congruency effects, general early sensory processing, or attentional effects (e.g., Ward et al., 2021; Brang, Edwards, Ramachandran, & Coulson, 2008; Brang, Kanai, Ramachandran, & Coulson, 2011; Sagiv & Ward, 2006; van Leeuwen et al., 2013; van Leeuwen, Petersson, & Hagoort, 2010). In this study, we use MEG to directly examine induced synaesthetic activity in order to advance our knowledge of its timing and proposed mechanisms. MEG serves as a happy medium between other neuroimaging techniques (i.e., fMRI and EEG), as it exhibits precise temporal resolution together with adequate sensitivity to the anatomical correlates of the measured signal.

We here designed an innovative MEG experiment and devised a novel analysis protocol to study the underlying brain mechanisms of grapheme-colour synaesthesia in six associator grapheme-colour synaesthetes. For this, we contrasted achromatic synaethsesia-inducing letters and non-inducing pseudoletters (in analogy to Brang et al., 2010). Our analysis approach was sensitive enough to capture even
weak, evoked neural activations related to the synaesthetic experience, while simultaneously remaining unbiased regarding any a-priori assumptions about the investigated brain locations. Additionally, due to strong inter-individual differences across associator synaesthetes, we performed the analysis on each participant separately, avoiding the smearing effects of group averaging. The core element of this novel MEG analysis protocol is Independent Component Analysis (ICA), a method for decomposing the multivariate multi-channel recordings into independent additive sub-components (Makeig, Debener, Onton, & Delorme, 2004; Makeig, Jung, Bell, Ghahremani, & Sejnowski, 1997). ICA is routinely used in the analysis of MEG data either for removal of artefacts or for analysis of resting state data (Brookes et al., 2012; Brookes et al., 2011; Capilla, Belin, & Gross, 2013; Spadone, de Pasquale, Mantini, & Della Penna, 2012; Vigario, Sarela, Jousmaki, Hamalainen, & Oja, 2000).

Here, ICA analysis was performed on the single-subject MEG data comprising both the synaesthesia-inducing and non-inducing stimuli sets together. This initial step results in sub-components of the data signal, each which reflect independent brain activity associated with some aspect of the MEG task. In order to isolate the sub-components potentially related to the induced synaesthetic percept, we identified those that exhibited a statistically significant difference between the two sets of stimuli (letters vs. pseudoletters). These sub-components of the data signal can be said to reflect brain activity dominated by the response to letters as opposed to pseudoletters. This unbiased selection of MEG data potentially related to the synaesthetic experience (i.e., that with statistically significant differences between inducing and non-inducing graphemes) comprises both “strong” and “weak” sub-components that represent a small portion of the total MEG data variance. In more conventional evoked-analysis approaches, such sub-components would be masked by much “stronger” evoked sub-components (representing a much larger portion of the MEG data variance). Each of the selected independent components, identified at the sensor level, are then projected to the entire source space (i.e., the entire brain) in order to localise their neural sources, without any a-priori selection of brain areas with expected effects. This analysis protocol was repeated for each individual participant. Overall, this novel MEG analysis protocol represents an unbiased, single-subject approach, with high sensitivity for investigating the sometimes subtle and heterogenous induced percept in synaesthesia.
Our results show an absence of early, visually evoked (extrastriate) activity in associator grapheme-colour synaesthetes (in response to synaesthesia-inducing letters vs. non-inducing pseudoletters). Instead, we find evoked activity dissociating inducing vs. non-inducing graphemes (in synaesthetes but not matched controls) to peak at approximately 190 ms and exhibiting an occipito-parietal topology localised consistently across individual synaesthetes to extrastriate visual cortex and the superior parietal lobes. Our findings provide evidence for a relatively late timing of induced synaesthetic activity, suggesting a Disinhibited Feedback model (or its variants) as underlying associator grapheme-colour synaesthesia.

2. Materials and Methods

All experiments were conducted in accordance with the ethical guidelines established by the Declaration of Helsinki, 1994, and were approved by the local ethical committee of the College of Science and Engineering, University of Glasgow. All participants gave their written informed consent prior to inclusion in the study. All participants had normal or corrected-to-normal vision, including normal colour vision.

2.1 Participants

Six grapheme-colour synaesthetes (age range: 19-34, all female, all right-handed), and six controls (age range: 21-35, m/f=1/5, all right-handed) matched on age, handedness and educational level participated in this experiment. Developmental synaesthesia was established by means of two questionnaires: in the first, participants rated statements describing aspects of their synaesthetic experiences and provided accompanying written explanations of these (questionnaire adapted from Banissy et al. (2009)), while in the second, they rated visual illustrations portraying their synaesthetic experiences (questionnaire adapted from Skelton et al. (2009)) and also provided short accompanying statements describing additional aspects of their synaesthetic experiences (see Supplementary Material for copies of both questionnaires). Based on both questionnaires, all six grapheme-colour synaesthetes were classified as associators according to the projector-associator distinction (Dixon, Smilek, & Merikle, 2004), but see (Eagleman, 2012). In addition, grapheme-colour
synaesthesia was tested and confirmed in all six individuals by means of a Consistency Test, which includes a surprise re-test (see Section, Consistency Test). At the conclusion of the study, all six controls were also screened for synaesthesia using the same written questionnaires administered to synaesthetes.

2.2 Consistency Test

The aim of the Consistency Test was to confirm grapheme-colour synaesthesia in all six synaesthetic participants using a test-retest reliability protocol, and to define synaesthetically inducing and non-inducing stimuli for the subsequent MEG task.

To this end, we used a computerized protocol adapted from Eagleman, Kagan, Nelson, Sagaram, and Sarma (2007), also providing normative data. Each trial began with the presentation of an achromatic grapheme (black on a medium grey background), together with a colour palette consisting of more than sixty-five thousand colours. Participants were instructed to select the colour that most closely matched their synaesthetic percept of the presented grapheme (or a “no colour” option if they lacked a colour experience for that grapheme). Participants were instructed to take their time and to be as precise as possible. Upon selection of a colour, the corresponding RGB value was automatically recorded and the next trial began. In total, there were 150 trials, corresponding to the full set of graphemes A-Z (26 total), the digits from 0-9 (10 total), and fourteen pseudo-letters (14 total) (see Figure 1), each repeated three times in randomised order. Matlab 2007b (The MathWorks, Inc.) was used to control both stimulus presentation and data collection.

After a minimum delay of three weeks, all six participants were re-tested in the exact same task. All grapheme-colour pairings were then tested for consistency, per synaesthete and across the two sessions based on the formula established by Eagleman et al. (2007): for each of the fifty graphemes (26 letters, 10 numbers, 14 pseudo-letters), the total distance between the selected colours (i.e., three colours per testing session) was calculated in normalised RGB colour space. Then, all colour distances were averaged within sessions (i.e., average of fifty colour distances for the first session, and average of fifty colour distances for the second) to yield Consistency Scores for each session; and subsequently the colour distances in both sessions together (i.e., data was concatenated across sessions) were averaged to yield a Consistency Score across sessions. All six grapheme-colour synaesthetes fell within
the normative synaesthesia range provided by Eagleman et al. (2007), i.e., exhibiting Consistency Scores below 1 (range of scores across sessions: 0.55-0.88).

2.3 Grapheme Stimuli
The set of stimuli was individually tailored to each synaesthete. First, seven colour-inducing letters and seven non-inducing pseudoletters were chosen for each synaesthete based on individual responses in the Consistency Test (i.e., those letters showing maximum consistency scores within and across sessions, and those pseudoletters showing no induced colours within and across sessions). Then, each of the seven colour-inducing letters was paired to one of the seven non-inducing pseudoletters, resulting in seven pairs of inducing/non-inducing graphemes (see Figure 2, Morph Levels 1 and 5). A sequence of “morphed graphemes” was created for each of these seven pairs, such that each of the seven stimulus sets consisted of one colour-inducing letter, one non-inducing pseudoletter, and three intermediate morphed graphemes, each representing a step-wise transformation between the preceding and succeeding grapheme pairs. These intermediate morphed graphemes were created such that they physically resembled a “blend” of the adjacent graphemes. This led to a total of thirty-five graphemes (7 stimulus sets x 5 graphemes per stimulus set) per synaesthete (also shown to individually age-matched controls). All graphemes were created manually, and were achromatic set against a medium grey background.

2.4 Psychophysics of the Synaesthesia-Inducing Stimuli
Following creation of the stimulus sets, all synaesthetes (but not controls) were asked to complete a computer task aimed at: 1) acquiring psychophysical measures of the synaesthesia-inducing and non-inducing nature of the presented stimuli across the five morph levels, and 2) defining the optimal duration of stimulus presentation for the subsequent MEG task (i.e. to minimize stimulus duration without compromising synaesthesia induction for synaesthesia-inducing graphemes).

Task (see also Figure 3): Participants were instructed to focus their attention to the centre of the screen. Each trial began with the presentation of an instruction screen (medium grey background) prompting the participant to press the “spacebar” key
when ready for the next trial. Upon the key-press, the stimulus appeared in black against the medium grey background. The stimulus was always one of the thirty-five pre-selected graphemes (i.e., from that particular synaesthete’s stimulus set). The stimulus remained on the screen for a pre-defined stimulus duration time (either 50 ms, 200 ms, or 1000 ms, randomized across trials). Fifteen repetitions were presented per stimulus and presentation time, which resulted in a total of 525 trials.

The task was two-fold. Synaesthetic participants were prompted first to indicate by button press whether the presented stimulus had induced a synaesthetic colour experience or not, by using two pre-defined (yes-no) keys; and second to rate, on a scale from 0 to 5, how strong their synaesthetic experience was via six other pre-defined keys (marked with labels 0-5). Synaesthetes were instructed to always respond with a ‘0’ if they had not experienced a synaesthetic colour, and to rate the strength of their synaesthetic colour experiences from 1 to 5 if they had answered “yes” to the previous question, with “1” being the weakest and “5” being the strongest synaesthetically induced colour experience. Synaesthetes were encouraged to use all five button presses and were reminded in every trial via on-screen instructions of the response-key assignments. Both questions, presented sequentially, remained on the screen until response. Synaesthetic participants were encouraged to take breaks, as the task lasted between 60-90 minutes, depending on individual pace.

2.5 MEG Task

During MEG recordings, grapheme-colour synaesthetes and matched controls viewed pairs of achromatic graphemes presented sequentially, while performing a grapheme comparison task of the two (Figure 4). The aim was to compare cortical processing of synaesthesia-inducing letters to non-inducing pseudoletters. Morphs were also presented in order to maintain participants’ attention to the presented graphemes (i.e., to increase the difficulty of the comparison task), but were not analyzed in terms of MEG responses.

In each trial, synaesthetes and controls viewed two successive achromatic graphemes, drawn from the pool of pre-selected graphemes (i.e., the individual stimulus set). The presented graphemes could thus be colour-inducing letters,
morphed graphemes, or non-inducing pseudoletters (i.e., any two graphemes within a stimulus set). Participants were instructed to compare the two presented graphemes on a scale from 1 to 5, where ‘1’ was “very similar” and ‘5’ “very different,” and the numbers ‘2,’ ‘3,’ and ‘4’ progressively dissimilar. Participants were encouraged to use all five buttons.

Stimuli were presented through a DLP projector (PT-D7700E-K, Panasonic) placed outside the shielded room onto a screen situated 1.90 m away from the participants via an in-room mirror. All stimuli (achromatic) were presented using Psychtoolbox (Brainard, 1977). Each trial began with the presentation of a black fixation cross against a medium grey background. After a delay of 1.5 s, the first grapheme (stimulus 1) was presented for 50 ms (duration selected based on the psychophysical pre-tests detailed above). After a delay of 2 s (with only the background screen remaining on the display), a second (different) grapheme (stimulus 2) was presented and remained until response. Upon response (using keys numbered 1-5), the background screen was again presented for 1 s before the next trial began (i.e., signalled by the presentation of a fixation cross). The fixation cross and graphemes were presented in the centre of the screen, and subtended a visual angle of 6 and 4 degrees, respectively.

Each grapheme was presented a total of twelve times as stimulus 1, and was paired with each of the other four related graphemes in its stimulus set three times (stimulus 2, separated by a blank screen, as described above). This led to a total of 84 trials (7 stimulus sets x 12 repetitions) per each of the five morph levels (synaesthesia-inducing letter, morph 2, morph 3, morph 4, non-inducing pseudoletter), and thus 420 trials in total (84 trials x 5 morph levels per stimulus set). Stimulus presentation was divided into six blocks, lasting 6-8 minutes each.

Participants were given instructions to maintain a steady gaze at the centre of the screen, and to blink immediately upon response. They were given unlimited time to rest between runs. On average, the total duration of the task was ~1 h.

2.6 MEG Recording
Brain activity was recorded with a 248-magnetometers whole-head MEG system (MAGNES® 3600 WH, 4-D Neuroimaging) confined in a magnetically shielded room. MEG signal was acquired at a 1017 Hz sampling rate.

Before starting the recording session, 5 coils were positioned on the participant’s head, which was localized at the beginning and end of each run. These coils, together with 3 fiducial points and the subject’s head shape, were digitized using a Polhemus system. During the recording session, participants were seated in a reclining chair and supported their head against the back and top of the magnetometer. Participants were asked to remain as still as possible and were continuously monitored by video camera. They were also instructed to minimize blinking during the presentation of visual stimuli, and instead to synchronize their blinks with the blank grey screen that immediately followed their response.

2.7 MEG Analysis

The analysis of the MEG signal was performed using the FieldTrip software package (Oostenveld, Fries, Maris, & Schoffelen, 2011) (see http://fieldtrip.fcdonders.nl/) and in-house Matlab code. It was performed in four main steps: 1) preprocessing aimed at removing artifactual activity; 2) an Independent Component Analysis (ICA) aimed at extracting the dominant patterns of brain activity; followed by 3) a Cluster-Level Analysis on the resulting event related fields (derived from single ICs) evoked by the synaesthesia-inducing (vs. non-inducing) visual stimuli; and, finally, 4) source-level analysis aimed at projecting single ICs into source space, and thus identifying the neural generators underlying the differences between conditions (inducing vs. non-inducing).

2.7.1 Preprocessing

Signals were first epoched in trials of 3 s length (1 s pre-stimulus), time-locked to the onset of the first stimulus in the pair (stimulus 1). We then removed the DC offset and linear trends in the signal to centre it around zero. To standardize the whole-signal preprocessing and facilitate subsequent source analysis, a common set of MEG sensors (n=8) manifesting low correlation with immediate neighbours (signifying increased levels of hardware noise) were removed from the MEG data set.
These MEG sensors were manually selected by computing the correlation between individual channels and their first and second order neighbours over the entire signal length (with bad trials removed, i.e., trials manifesting a variance three z-scores above the average variance, per channel). Then, trials contaminated with SQUID jumps were discarded from further analysis, and the remaining MEG signal was de-noised relative to the MEG reference sensors, as implemented in the “ft_denoise_pca” function in FieldTrip. Finally, trials with large signal variance were removed from the MEG data set prior to implementing ICA to isolate and reject both eye blinks and cardiac components from the MEG signal (“fastica” algorithm implemented in FieldTrip, after a dimensionality reduction to 20 components).

2.7.2 Independent Component Analysis (ICA) for Analysis of Evoked Signals

In the case of comparing two experimental conditions, as is done here, performing ICA to each of the conditions separately could lead to the undesired situation in which the decomposition of a component was not performed in exactly the same numerical way for both conditions. In such a case, it becomes difficult both to identify and compare components underlying a brain process present in both conditions, but dominant in only one. For these reasons, ICA was performed on the entire data set before isolating the conditions of interest (Inducing vs. Non-Inducing).

Specifically in this study, ICA has been employed to isolate components present in both conditions of interest, on a single-subject level. All components are then compared across the conditions of interest (Inducing vs. Non-Inducing Graphemes), in order to identify components dominated by one condition versus the other. Thus, following the preprocessing of the raw data, the “cleaned” data were downsampled to 250 Hz and subjected to an ICA (“runica;” FieldTrip/EEGLAB, http://sccn.ucsd.edu/eeeglab/) in a time window between -0.3 s and 1.2 s. This algorithm first performs a PCA-based dimensionality reduction to 40 components, and then performs ICA on these 40 components. For each participant, the resulting data (from the ICA) were filtered between 1-50 Hz, since only event-related averages were of interest; and finally, single trials in each ICA component were averaged separately for both conditions (Inducing vs. Non-Inducing).
2.7.3 Nonparametric Cluster-Based Permutation Analysis (ICA Space)

We then applied a nonparametric cluster-based permutation analysis (Maris & Oostenveld, 2007), as implemented in FieldTrip, to the resulting single-subject data (i.e., from each participant’s ICA) in order to identify clusters of time in which the two conditions of interest (Inducing vs. Non-Inducing) exhibited significant differences (time window of interest, 70-320 ms). This test controls the family wise error rate (FWER) in the context of multiple comparisons. For each permutation (n=1000), time clusters are defined on the basis of temporal adjacency by regrouping samples whose t-values correspond to (or exceed) a p-value of 0.05. Cluster-level statistics are then calculated by taking the sum of t-values within the cluster. Here, only temporal clusters with corrected p-values \( \leq 0.025 \) are reported (note that the 97.5\(^{th}\) quantile corresponds to the threshold for a two-sided parametric t-test at critical alpha-level 0.05, as was performed here). For each participant, only ICs surviving the cluster-based permutation analysis (p<0.05) were kept and further examined (timing of significant differences, inverse solution for individual ICs).

2.7.4 Timing of Significant Differences between Inducing and Non-Inducing Conditions within Independent Components (ICs)

In order to further refine the selection of significant ICs across participants, the time window of maximal temporal overlap across participants’ significant clusters was identified. Importantly, this allowed identification of the time period in which processing of the Inducing grapheme differed from that of the Non-Inducing grapheme across all participants. To this end, all ICs exhibiting significant differences between conditions were grouped together independently for each group (Synaesthetes vs. Controls), and the distribution of significant time points (i.e., time points corresponding to significant differences between conditions) was plotted in time-bins of 20 ms. The time window corresponding to maximum temporal overlap (across participants’ significant clusters) was thus identified, and only corresponding ICs were further analysed (i.e., those containing significant clusters at least partially falling within the identified time window).

2.7.5 Topography of Significant Independent Components (ICs)
The grand average of these ICs was then calculated individually for each group by projecting ICs back to sensor space on a single-subject level. Planar gradient magnitudes were then computed considering first- and second-order neighbouring sensors (maximum distance of 7.4 cm) using the “sincos” approach implemented in FieldTrip, before the resulting data were averaged across participants of each group. The aim here was to identify and compare the average brain activity and topography in this (highly significant) time period across individual participants of each group, and also between groups.

We clarify that the grand averages reported here do not entail or represent any statistical group analysis. Statistical significance is only assessed on the individual-subject level (due to strong inter-individual differences across associator synaestheses). As ICA is performed for each participant separately, it is possible that the identified significant ICs represent different underlying neural processes with variable topographies, but which are all related to processing of synaesthesia-inducing versus non-inducing graphemes. Thus, the grand averaging of all significant ICs across participants here is performed only to depict an overview of the areas activated across the different groups of participants. This analysis is merely a depiction, or a single summarised map, of all significant activations.

2.7.6 Source Level Analysis

The ICs (for each participant) showing significant differences between conditions were localized in source space using a weighted-Minimum Norm Least Squares Estimation (wMNLS). The brain source space was created by constructing a semi-realistic single shell head model (Nolte, 2003) from each participant’s own MRI image.

2.7.7 MEG-Magnetic Resonance Image Co-Registration

T1-weighted structural magnetic resonance images (MRIs) of each participant were co-registered to the MEG coordinate system by a semi-automatic procedure that provided the best fit between the participant’s scalp surface, extracted from his/her anatomical MRI, and the digitized head shape from the MEG. To obtain a first approximate alignment between MEG and MRI coordinates, we manually located the
three digitized fiducial points (nasion, left and right pre-auricular points) in each individual’s MRI.

### 2.7.8 Head and Forward Models

The brain was segmented using the segmentation routine implemented in FieldTrip/SPM8 ([http://www.fil.ion.ucl.ac.uk/spm](http://www.fil.ion.ucl.ac.uk/spm)). Cortical surfaces were first extracted with the FreeSurfer image analysis suite, which is documented and freely available for download online ([http://surfer.nmr.mgh.harvard.edu/](http://surfer.nmr.mgh.harvard.edu/); Reuter et al., 2012). Then, the source space spanning the cortical sheet was created using the MNE-suite software (Gramfort et al., 2013; Dale et al., 1999), which by using the topology of a recursively sub-divided icosahedron on the cortical surface, inflated to a sphere, selects the subset of vertices that define the source space. In this work, the original cortical sheet point set from the Freesurfer segmentation was downsampled to a total of 8,196 vertices for each individual. We then constructed a semi-realistic single shell head model (Nolte, 2003) based on each individual’s brain. Finally, we computed the lead fields corresponding to the 2 tangential orientations for each voxel.

### 2.7.9 Inverse Solution (Source Space)

The aim of the inverse solution, as used here, is to project single ICA activity into source space using a methodology similar to that previously applied to resting state MEG data (de Pasquale et al., 2010; Mantini et al., 2011), in which a weighted-Minimum Norm Least Squares Estimation (wMNLS) is employed (Lin et al., 2004), but with a different regularization parameter for each IC. In particular, each map of the IC spatial weights is projected from sensor to source space through wMNLS and the regularisation parameter is computed based on the distribution of the IC weights (for details, please see Appendix). The inverse solution was computed in MATLAB using the Fieldtrip toolbox (Oostenveld et al., 2011).

### 3. Results

#### 3.1 Psychophysics of the Synaesthesia-Inducing Stimuli
As expected, the proportion of trials in which synaesthetes indicated a synaesthetic experience decreased across the 5 five morph levels, with optimal duration of stimulus presentation being 50 ms (i.e. minimum stimulus duration without compromising synaesthesia induction for synaesthesia-inducing graphemes). (grapheme-colour synaesthetes collapsed; stimulus duration time = 50 ms; letters, morph 2, morph 3, morph 4, pseudoletter: 91.43 % ± 5.47, 90.95 % ± 5.49, 84.76 % ± 7.18 %, 66.19 % ± 11.10, 40.95 % ± 12.96), as did the mean strength of subjective synaesthesia-experience (max=5, min=0) (3.43 ± 0.54, 3.03 ± 0.48, 2.54 ± 0.42, 1.79 ± 0.433, 0.82 ± 0.32). Comparing the strength of synaesthetic sensations between letters and pseudoletters for synaesthetic participants (n=6) (group-level paired samples t-test) revealed a significant difference (t(5)=4.62, p=0.005), confirming that letters did indeed induce a synaesthetic experience, while pseudoletters either did not (synaesthetic strength=0) or only did so very weakly, as intended per design.

3.2 Non-parametric Cluster-Level Permutation Analysis on ICs

The single-subject level ICA on the cleaned, raw signal yielded 40 independent components (ICs) per participant, of which on average 1.6 ICs in Synaesthetes proved to show significant differences between synaesthesia-inducing and non-inducing stimuli (vs. on average 1 IC in Controls), according to a non-parametric cluster-level permutation analysis. Therefore, Synaesthetes generally exhibited more significant ICs than Controls, with all Synaesthetes (but not all Controls) exhibiting at least one significant IC (compare 10 total significant ICs observed in all 6 Synaesthetes vs. 6 total significant ICs observed in only 4 out of 6 Controls) (Figures 5 and 6).

3.3 Timing of Significant Differences between Inducing and Non-Inducing Conditions within Independent Components (ICs)

In order to identify the time window of maximal temporal overlap across participants’ significant clusters (i.e., the time period in which significant differences between conditions generally manifested across participants), all ICs containing significant clusters (i.e., significant differences between conditions) were grouped together (independently for each group, Synaesthetes vs. Controls). First, the entire
analysed time window (70-320 ms) was divided into bins of 20 ms. Then, the time points of significant clusters were grouped into the specified time-bins (i.e., 70-90 ms, 90-110 ms, 110-130 ms, etc.). The total number of significant clusters falling within each time-bin was counted, normalised according to the total number of participants in each group (n=6 for each), and plotted (Figure 7).

Figure 7 thus illustrates the number of clusters (within ICs) that show significant differences between Inducing and Non-Inducing graphemes across the analysed time window (70-320 ms), in bins of 20 ms, for each group. We report three main findings from this analysis. First, significant differences in processing of Inducing and Non-Inducing graphemes occur in synaesthetes predominantly in a late time window, peaking at around 190 ms (ranging between 130-230ms). Second, the histogram demonstrates that synaesthetes show more significant differences than controls. Third, controls showed a similar timing for differences between both experimental conditions but with fewer ICs.

3.4 Topography of Significant Independent Components (ICs)

Since the maximum temporal overlap of significant clusters across participants in both groups centred at approximately 190 ms and the majority of clusters fell within 130-230ms, the grand average of all corresponding ICs (i.e., those containing significant clusters at least partially falling within the time window, 130-230 ms) was calculated individually for each group, in order to identify and compare the average brain activity and topography in this (highly significant) time period across individual participants of each group. Figure 8 illustrates the topographies and signal differences of Synaesthetes and Controls between conditions (Inducing vs. Non-Inducing) within the pre-selected time window (130-230 ms). While the topographies in panel (a) show the contrast between conditions (Inducing minus Non-Inducing) for each group independently (Synaesthetes and Controls), the topography in panel (b) shows the difference between these (Synaesthetes minus Controls), revealing increased activity in Synaesthetes (vs. Controls) in occipito-parietal areas.

Here, we note that these topographies are the concatenated significant activity from individual participants and not common activity across all of them. Thus, Figure
8 should not be seen as a group statistical analysis, as all statistical analysis was performed at the single-subject level and is presented in Figure 7. Instead, it is simply a summarising map of all superimposed topographies (of significant individual components). This overview shows that all identified significant components are localised to posterior, occipito-parietal regions. While the activated areas are not common across all participants, individual areas are all coarsely located in this part of the brain. The following section presents, for each individual participant, where the significant activity is localised in source space.

3.5 Source Level

The wMNLS source reconstruction, performed on a single-subject level, yielded consistent sources across the five Synaesthetes (of 6) who showed ICs in the 130-230 ms window (n=5, see Figure 9). As indexed by the Talairach Tournoux atlas (Talairach & Tournoux, 1988), these were localized to visual extrastriate cortex overlapping with Brodmann area 19 in the occipital lobe (in five Synaesthetes) and Brodmann area 7 in the superior parietal lobe (in three Synaesthetes). In contrast, source reconstructions across the three Controls (of 6) who showed ICs in the 130-230 ms window were less consistent (see Figure 10), localizing instead to Brodmann area 18 in the occipital lobe in one participant, to Brodmann area 40 in the inferior parietal lobe in a second participant, and to both areas in a third.

Note that the scaling of Figures 9 and 10 reflect Z-scores of the projected IC weights. What are projected through the inverse solution into source space are the weights of single ICs. The spatial filters are derived through wMNLS, which uses the forward solution as a model for propagation (from the brain to the sensors). This inverse solution translates the magnetic field measurements outside the brain into activation inside the brain. In our case, we multiply the unit-less set of numbers (i.e., weights of ICs) with this inverse solution; consequently, these numbers (i.e., the weights of the ICs) are scaled by the spatial filter of the inverse solution. As the IC weights are unit-less, this scaling does not produce a physical quantity inside the brain (such as power), but rather a set of linearly combined, scaled weights. In order to make these results more interpretable, we add a further scaling by using the Z-score of
the projected numbers. This further scaling provides a better interpretation of the distribution of the projected weights on the cortical sheet.

4. Discussion

We here carry out an MEG study on associator grapheme-colour synaesthetes in whom we examine the neural activity dissociating the perception of synaesthesia-inducing letters from non-inducing pseudoletters. Overall, we find that the neural processes differentiating between inducing and non-inducing graphemes occurs relatively late in the processing hierarchy, peaking approximately at 180-200 ms, well after grapheme identification is likely complete (Rey, Dufau, Massol, & Grainger, 2009) and consistent with the reported timing of the synaesthetic colour concurrent in a recent MEG classification study (Teichmann et al., 2021). Due to the late timing of these effects, they do not likely occur during the initial, feed-forward sweep of activity in the visual processing stream (see Lamme & Roelfsema, 2000), as predicted by models of synaesthesia invoking rapid timing predictions (i.e., Cross-Activation/CCT models). In addition to examining the timing of induced synaesthetic activity, we performed source reconstruction of the corresponding signals. We report consistent involvement of occipito-parietal areas, localising to extrastriate visual cortex in the occipital lobe and coinciding with activity in the superior parietal lobules. These anatomical correlates could implicate multisensory convergence zones in the dissociation between synaesthesia-inducing and non-inducing graphemes.

Only two MEG studies to-date (Teichmann et al., 2021; Brang et al., 2010) have examined the induced synaesthetic percept via the presentation of achromatic, synaesthesia-inducing graphemes. Brang and colleagues (2010) showed activity in pre-defined area hV4 peaking between 111-130 ms, only 5-ms after the onset of activity in pre-defined grapheme areas. In contrast to our study, these findings support a model of synaesthesia that hypothesises early and rapid activation of the involved brain areas in response to inducers, such as Cross-Activation (as proposed by Brang and colleagues (2010)) or models describing a breakdown in modularity between presumably separate and independent brain areas (Baron-Cohen et al., 1993). One important distinction between our studies is that the four grapheme-colour
synaesthetes who were included in Brang et al. (2010) were strong projectors, while those who participated in ours were considered associators. Thus, we speculate that the inconsistency in our findings could reflect differences in phenomenology between sub-types, as has been previously proposed (see van Praag et al., 2016). Associators differ from projectors in that their synaesthetic qualia are more conceptual than perceptual and are generally experienced in their mind’s eye rather than in external space. It is thus possible that different models account for different synaesthetic sub-types, given their differences in phenomenology, measured behaviour, and differential white matter connectivity (Rouw et al., 2010; Rouw et al., 2007). Recently, differences in the timing and experience of photisms between projectors and associators was also shown (Lungu et al., 2021). In contrast, Teichmann and colleagues (2021) used classification models on a larger group of grapheme-colour synaesthetes to examine the timing of induced colours; they reported a later time period (around 200 ms) as corresponding to the induced synaesthetic activity.

The difference topography between Synaesthetes and Controls (derived from the group averages of all ICs exhibiting significant differences between conditions) implicates occipito-parietal areas (see Figure 8) peaking at ~190 ms. Furthermore, localisation of significant ICs via a Minimum Norm inverse solution (single-subject approach) consistently yielded areas in extrastriate occipital cortex and both inferior and superior parietal lobes (Figure 9). The superior parietal lobes have been implicated in the (spatial) co-localization of visual features into coherent percepts (i.e., feature conjunction tasks) (Baumgartner, 2013; Robertson, 2003; Donner et al., 2002; Shafritz et al., 2002; Corbetta et al., 1995) and, importantly, have been causally implicated in the binding of colours to letters in grapheme-colour synaesthesia (Esterman, Verstynen, Ivry, & Robertson, 2006; Muggleton, Tsakanikos, Walsh, & Ward, 2007; Rothen, Nyffeler, von Wartburg, Muri, & Meier, 2010). In fact, there is increasing evidence showing the importance of parietal cortex in associator grapheme-colour synaesthesia, particularly the superior parietal and intraparietal sulcus (IPS) regions (van Leeuwen et al., 2010; Weiss et al., 2005; Zeki & Marini, 1998), including anatomical studies showing increased coherence (FA) in the white matter of IPS (Rouw & Scholte, 2007), and functional connectivity studies (Jancke & Langer, 2011; Specht & Laeng, 2011) demonstrating important hubs in parietal areas.
(in addition to corresponding early sensory areas, such as fusiform gyrus). Thus, parietal cortex seems to play a crucial (essential) role in the induced synaesthetic percept of associator synaesthetes, either in the hyperbinding of visual features elicited in earlier visual areas, or in feedback to earlier visual areas.

In our study, the lateralisation of occipital and parietal areas varied between synaesthetes. Our single-subject ICA approach made no \textit{a priori} assumptions about the underlying neural activity of the synaesthetic percept or of its location within the brain. Thus, while this approach allowed for inter-individual differences to be expressed (often missing in synaesthesia studies), it also resulted in a heterogenous selection of anatomical regions across participants. This limits our ability to allocate the functional loci of our findings onto common brain areas across all synaesthetes, as it is possible that the activity captured by ICs across individuals reflected differing processes related to the induced synaesthetic percept. Having said this, previous neuroimaging studies have reported similar findings (see (Gray et al., 2006; Zeki & Marini, 1998)) and in fact, both veridical as well as synaesthetic colour have been found to maximally activate a broad range of areas in ventral occipitotemporal cortex, in both hemispheres (see van Praag et al., 2016 and Rouw et al., 2011, for a review). Synaesthesia is highly idiosyncratic and individual differences between synaesthetes are common in the literature (both in behaviour and neuroimaging) (van Praag, 2016; Rouw & Scholte, 2010; Sperling et al., 2006; Hubbard et al., 2005; Dixon et al., 2004), including lateralisation.

Contrary to Synaesthetes, the three Controls who also displayed significant differences between conditions showed no consistency in their inverse solutions (Figure 10), possibly reflecting task-specific strategies, slight differences in activity reflecting letters versus pseudoletters, or possibly further supporting a model of synaesthesia invoking enhanced activity in universally-present neural pathways (i.e., akin to Stochastic Resonance). We did not expect to observe early visual differences between conditions (Inducing vs. Non-Inducing) based solely on grapheme recognition, given (1) the physical similarity between letters and pseudoletters in terms of low-level visual complexity, (2) current theories of grapheme recognition as a process of hierarchical feature analysis, and (3) the lack of letter-centred or language-centred task demands (note that 80% of presented graphemes were
pseudoletters, or morphed graphemes) (Dehaene et al., 2005; Hubbard et al., 2005; Mitra & Coch, 2009) (but see Rey et al., 2009). Nonetheless, we cannot rule out the possibility that observed differences between conditions reflect visual processing differences unique to grapheme-colour synaesthesia, but not specifically related to induced, conscious colour concurrents. Since our paradigm did not directly address the “consciousness” or phenomenological experience of the synaesthetic concurrent itself, these are here not dissociable from general processing differences between inducing and non-inducing stimuli.

We here present evidence for the relatively late timing of induced activity in associator grapheme-colour synaesthetes, more in line with models like the Disinhibited Feedback model, implicating functional (as opposed to structural) differences between synaesthetes and non-synaesthetes. This is consistent with models proposing common mechanisms of cross-modal integration across synaesthetes and non-synaesthetes alike. In sum, our study is the first MEG study to date revealing stimulus evoked activity in associator grapheme-colour synaesthetes in a network of areas including the occipital and parietal cortices, peaking relatively late (~190 ms) in the visual processing stream of events and thus advancing our ability to disentangle between current models of synaesthesia.

Appendix

Minimum Norm Inverse Solution for Single Independent Components

The weighted Minimum Norm Least Squares (wMNLS) solution is computed according to (see Lin et al., 2004):

\[ W = R_a \cdot \Lambda^T \cdot (\Lambda \cdot R_a \cdot \Lambda^T + \lambda^2 \cdot C)^{-1} \]

where

- \( \Lambda \) : Leadfield matrix
- \( R_a \) : a priori assumed brain source covariance
- \( C \) : noise covariance in MEG sensor array
- \( \lambda \) : Minimum Norm regularisation parameter

In our work, we followed a novel approach for the computation of the regularization parameter for each IC, according to the following equation:

\[ \lambda = 0.5 + \sqrt{\frac{\text{trace}(\Lambda \cdot R_{\text{scaled}} \cdot \Lambda)}{\text{trace}(C) \cdot \text{pseudoSNR}}} \]

where \( R_{\text{scaled}} \) is the a priori assumed brain source covariance matrix scaled as:

\[ R_{\text{scaled}} = R_a \cdot \frac{\text{trace}(C)}{\text{trace}(\Lambda \cdot R_a \cdot \Lambda)} \]

so that

\[ \frac{\text{trace}(\Lambda \cdot R_{\text{scaled}} \cdot \Lambda)}{\text{trace}(C)} = 1 \]

Consequently, the regularization parameter formula is reduced to:

\[ \lambda = 0.5 + \frac{1}{\text{pseudoSNR}} \]

and the inverse solution becomes:

\[ W = R_{\text{scaled}} \cdot \Lambda^T \cdot (\Lambda \cdot R_{\text{scaled}} \cdot \Lambda^T + \lambda^2 \cdot C)^{-1} \]
where \( \text{pseudoSNR} \) is a scalar parameter used to represent a pseudo Signal-to-Noise ratio for a single IC.

As the noise power within a single IC is unknown, here we chose to derive an empirical measure of how well an ICA represents a few strong focal brain sources or widely distributed noise. For an ICA representing a strong focal brain dipole, the squared ICA unmixing weights have a skewed distribution, with high values at the sensors close to the underlying sources, and all the rest of the sensors (further from the underlying sources) having much lower values. In the case of an IC capturing widely distributed noise, the squared ICA unmixing weights have more comparable values. Consequently, the upper, i.e. 70 \%, and lower, i.e. 30 \%, distribution percentiles are expected to be more distant in the case of a brain activity IC than in the case of a noise IC.

This parameterization has been used in order to estimate a pseudo Signal-to-Noise Ratio for a single IC. If the squared unmixing ICA coefficients for a single ICA are represented by \( Uica^2 \), then the \( \text{pseudoSNR} \) is computed as:

\[
\text{pseudoSNR} = \sqrt{\frac{\text{prctile}(Uica^2, 70\%) - \text{prctile}(Uica^2, 30\%)}{\text{prctile}(Uica^2, 30\%)}}
\]

This parameter has a lower bound of 0. The higher the distance between the percentiles, the higher the value of this parameter. The closer the upper and lower percentiles get, the closer this parameter is to this lower bound.

From the formula for the regularisation parameter, the latter term \( 1/ \text{pseudoSNR} \) varies in an inverse fashion, from 0 to high positive values. This means that for ICs representing strong dipolar sources, little regularization is used, as the unmixing matrix contains a clear dipole representation. For ICs representing noise, a higher regularization is used as the unmixing matrix represents a more complex and distributed pattern.
Having very small regularisation values close to 0 for very strong dipoles can lead to instability in the derivation of the inverse solution. In order to avoid such instabilities, a scalar value of 0.5 has been added to $1/\text{pseudoSNR}$ in the derivation of the regularization parameter. This value represents the $1/\text{pseudoSNR}$ ratio when the difference ratio between the upper and lower percentiles under the square root in $\text{pseudoSNR}$ is equal to 4.

With this final formulation, the regularisation parameter varies between 0.5 (for ICs representing strong brain sources) and infinity (for ICs representing noise). Infinity here just represents very high values. This is because in ICA unmixing matrices, the 30 % and 70 % percentiles cannot have the exact same values, as this would require that all the in between weights in the distribution should be identical.

The above described regularisation parameter has a lower bound, which hedges against instabilities of the inverse solution, and no upper bound, which allows for high regularisation when ICA components representing noise are localised.

The above described inverse solution procedure was applied to each of the ICs, for which a significant statistical difference was found in the comparison between the compared conditions, both for synaesthetes and controls. No a priori brain sources covariance was assumed, so $R_s$ was the identity matrix with dimensions $N_{sources} \times N_{sources}$. As the level of noise in the single ICs was also unknown, the noise covariance matrix $C$ was the identity matrix as well, with dimensions $N_{sensors} \times N_{sensors}$. The source localization was performed and plotted on the 3-dimentional template grid with 6mm resolution, warped to each subject’s brain volume.
Figure 1. Pseudo-letters presented to grapheme-colour synaesthetes in Consistency Task. These were manually created using component features similar to letters.
Figure 2. Morph Sets. Seven static sequences of morph graphemes were created for each grapheme-colour synaesthete, such that each complete “morph set” consisted of a colour-inducing letter, a non-inducing pseudo-letter, and three “intermediate” morph graphemes representing step-wise transformations between the inducing letter and the non-inducing pseudo-letter. The intermediate morph graphemes were created such that they physically resembled a “blend” of their preceding and subsequent graphemes.

Figure 3. Task used in Psychophysical Testing of MEG Stimuli.
Figure 4. Task administered to grapheme-colour synaesthetes and controls in MEG. Participants were instructed to attend to all stimuli and rate the similarity between presented graphemes (on a scale from 1-5) following the presentation of the second one.
**Figure 5.** Independent Components of Synaesthetes: Topographies and Time-Series. (a) Represented are the topographies of those ICs exhibiting clusters with significant differences between conditions (Inducing, Non-Inducing) in Synaesthetic participants. (b) Represented are the time series of the same ICs. The shaded areas represent clusters of time in which significant differences between conditions (Inducing, Non-Inducing) occurred. The lighter shading corresponds to ICs with time periods outside the window of maximal temporal overlap (see Figure 7). Note that values on the y-axis correspond to an order of 10e-12 (arbitrary units).

**Figure 6.** Independent Components of Controls: Topographies and Time-Series. As Figure 5, but for Control participants.
Figure 7. Maximal Temporal Overlap of ICs. Bar plots for each group (Synaesthetes, Controls) showing the frequency of significant clusters (within ICs) for the entire analysed time window (70-330 ms), in bins of 20 ms and normalised to number of participants in each group (n=6).
Figure 8. Contrast between Inducing and Non-Inducing Conditions. The topographies and signal differences between conditions (Inducing vs. Non-Inducing) within the pre-selected time window (130-230 ms) are shown. (a) Contrast between conditions (Inducing minus Non-Inducing) for each group independently (Synaesthetes, Controls). (b) Contrast between groups (Synaesthetes minus Controls). Note that this difference plot is a difference (Synaesthetes minus Controls) of two differences (Inducing minus Non-Inducing, for each group).
Figure 9. wMNLS source reconstructions in individual Synaesthetes. Five out of six Synaesthetes exhibited ICs with significant differences between conditions. The inverse solutions of these individual ICs are shown. All Synaesthetes but one (Syn.1) exhibited sources both in the occipital and parietal lobes.
**Figure 10.** wMNLS source reconstructions in individual Controls. As in Figure 9, but for Controls. In contrast to Synaesthetes, sources across the three Control participants were inconsistent, localizing to differing occipital, temporal, and parietal areas.
