Accepted manuscript

As a service to our authors and readers, we are putting peer-reviewed accepted manuscripts (AM) online, in the Ahead of Print section of each journal web page, shortly after acceptance.

Disclaimer

The AM is yet to be copyedited and formatted in journal house style but can still be read and referenced by quoting its unique reference number, the digital object identifier (DOI). Once the AM has been typeset, an 'uncorrected proof' PDF will replace the 'accepted manuscript' PDF. These formatted articles may still be corrected by the authors. During the Production process, errors may be discovered which could affect the content, and all legal disclaimers that apply to the journal relate to these versions also.

Version of record

The final edited article will be published in PDF and HTML and will contain all author corrections and is considered the version of record. Authors wishing to reference an article published Ahead of Print should quote its DOI. When an issue becomes available, queuing Ahead of Print articles will move to that issue's Table of Contents. When the article is published in a journal issue, the full reference should be cited in addition to the DOI.

Abstract

Comprehensive field investigations into the axial cyclic loading behaviour of open-steel pipe piles driven and aged in low-to-medium density chalk identify the conditions under which behaviour is stable, unstable or metastable. Post-cycling monotonic tests confirmed that stable cycling enhanced pile capacity marginally, while unstable cases suffered potentially large losses of shaft capacity. Metastable conditions led to intermediate outcomes. The patterns by which axial deflections grew under cyclic loading varied systematically with the normalised loading parameters and could be captured by simple fitting expressions. Cyclic stiffnesses also varied with loading conditions, with the highest operational shear stiffnesses falling far below the in-situ seismic test values. The monotonic and cyclic axial responses of the test piles were controlled by the behaviour of, and conditions within, the reconsolidated, de-structured, chalk putty annuli formed around pile shafts during driving. Fibre-optic strain gauges identified progressive failure from the pile tip upwards. Large factors of safety were required for piles to survive repetitive loading under high-level, two-way, conditions involving low mean loads, while low amplitude one-way cycling had little impact. A simple 'global' prediction procedure employing interface shear and cyclic triaxial tests is shown to provide broadly representative predictions for field behaviour.

Keywords: Chalk; driven piles; cyclic loading

INTRODUCTION

Chalk outcrops over a wide area of northern Europe and in other regions worldwide. Bridge, port, offshore and other structures constructed at chalk sites often rely on open-ended driven steel pile foundations that may sustain significant load cycling. Offshore structures experience repetitive wind and wave loads, while wind-turbines impose tens of millions of blade rotation load cycles.

The impact of cyclic loading on piles driven in chalk appears potentially significant. Burland & French (1990) report a one-way axial cyclic test in Luton, UK, which reduced the tension capacity of a small steel pile by 60% within 20 cycles. Steel 762mm diameter piles driven at St Nicholas-at-Wade (SNW, near Margate in Kent) which had been tested to failure 19 months earlier (Ciavaglia et al. (2017a, b)) showed up to 93% shaft capacity losses after modest numbers (N) of two-way axial cyclic loading cycles (Iberdrola (2013), Buckley (2018)). However, Lahrs & Kallias (2013) report that cyclic loading applied to a 1.5m diameter steel tubular pile driven at Hemmoor, Germany led to essentially stable outcomes, although their test pile had undergone dynamic re-strike tests between its installation and cyclic testing. Further research was clearly required; this paper reports two comprehensive studies into the conditions under which axial cyclic loading affects load carrying performance negatively and shows how its effects may be assessed in practice.

Recent research into driven pile behaviour in chalk

Considerable difficulties exist in understanding and predicting the monotonic or cyclic behaviour of piles driven in chalk. Jardine et al (2018) identified the poor reliability of industry standard design methods and emphasised the wide ranges of outcomes observed in the field. They summarised findings from limited monotonic and dynamic field-testing programmes they conducted in low-to-medium density chalks at SNW and the Wikinger Baltic Sea offshore windfarm, noting:

- Chalk de-structures under percussive driving and forms very soft putty annuli around pile shafts. Very low local shaft resistances develop that fall steeply with increasing relative pile tip depth, *h/R*

- Marked shaft capacity gains, or set-up, develop as piles age after driving

- Local tip and shaft radial effective stresses vary directly with CPT tip resistance q_t

- Local shaft resistances are governed by a Coulomb law, with interface shear angles that can be measured in laboratory interface shear tests

- Constrained interface dilation also contributes to shaft resistance

- The CPT-based, effective-stress, Chalk ICP-18 axial capacity framework (Jardine et al., 2018) appeared to capture the above features adequately, although further field research was required to develop reliable practical design procedures.

Buckley et al. (2018a) describe a parallel programme of cyclic testing at SNW that offered the first systematic study of how 'virgin' open-driven steel piles respond to repetitive tension loading in chalk. Experiments were conducted on seven, fully-aged, 139mm outside diameter (D) un-instrumented steel tubular 'SD' piles driven above the water table to 5.5m tip depths (L_p) giving $L_p/D \approx 40$. The piles had ≈ 9mm wall thicknesses (t_w) and $D/t_w \approx 15.4$. Static reference tests on control piles confirmed that monotonic capacity developed after ≈ 250 days of ageing after driving and identified the reference static tension capacities available prior to applying up to 1,000 cycles.

The most severe one-way tension cycling led to unstable (US) outcomes when the 'static factors of safety', FoS defined as Q_{max}, the maximum cyclic tension load, divided into Q_{ref}, the static reference tension capacity, fell below ≈ 1.45. Pile displacements accumulated rapidly, axial stiffnesses fell, and failures developed with N<100. Piles subjected to one-way cyclic loading with $1.45 <$ FoS < 2.1 remained un-failed after 1,000 cycles. Their displacements accumulated broadly in proportion to $N^{0.33}$ for the limited range of conditions considered. Test outcomes were classified as being either stable (S) or meta-stable (MS) according to their displacement and the capacity trends proven by post-cyclic static tests: cycling could either improve or degrade axial capacity.

Buckley et al (2018) were not able to explore either two-way cycling, which was expected to lead to more marked cyclic degradation, or the response of larger diameter piles. Both issues were considered critical to practical application.

The ALPACA programme

The ALPACA (Axial-Lateral Pile Analysis for Chalk Applying multi-scale field and laboratory testing) and ALPACA Plus Joint Industry research projects (JIPs) outlined by Jardine et al. (2019) tackled the axial-and-lateral, dynamic, cyclic and monotonic behaviour of mostly tubular steel, piles with diameters ranging from 139mm to 1.8m. Over 40 piles were driven at SNW between 2017 and October 2020 to depths both above and well below the water table. Most were equipped with strings of closely spaced fibre-optic strain gauges; Jardine et al (2023) report the site layout and identify the piles assigned to phased monotonic-and-cyclic, axial and lateral, testing between May 2018 and December 2021.

Outcomes from ALPACA monotonic axial experiments

Twenty-two 'virgin' corrodible steel piles were subjected to monotonic axial testing. Four stainless steel and concrete piles were driven and tested to isolate the potential impact of corrosion processes. Jardine et al (2023) describe how pore-pressure dissipation, effective stress re-distribution and long-term corrosion processes control axial set-up and led to quite different ageing trends above and below the water table. Other key observations include: (i) Chalk ICP-18 approach provided good predictions for driving resistances, (ii) long-term compression shaft capacity is around double that available in tension, as reported at other chalk sites by Vinck (2021), (iii) long-term local shaft stresses decline

more sharply with *h/R* than expected by Chalk ICP-18, (iv) closed piles develop far higher capacities than open-ended equivalents and (v) base capacities also show some set-up. Jardine et al (2023) applied these findings in a comprehensive recalibration of Chalk ICP-18.

ALPACA AXIAL CYCLIC PROGRAMME

This paper reports the ALPACA one-way tension and two-way (compression and tension) testing on fourteen 'virgin' open-steel 139 and 508mm OD piles, supported by monotonic control tests, integrating their outcomes with the Buckley et al. (2018) study. Noting that open tubular driven piles develop far higher compressive than tensile shaft capacities in chalk and that cyclic tension cases are the most critical for light-weight offshore wind-turbines (Barbosa et al. 2017), the programme focussed on conditions where the loading was more onerous in tension than in compression. All the pile movements induced by cycling were consequently vertically upwards.

Test ground conditions

Principally CIRIA grade B2 (Lord et al., 2002) structured, very weak-to-weak, low-to-medium density white chalk extends to well below the test pile tips. The chalk has a high degree of saturation above the water table, which is located at ≈0.9m±0.25m Above Ordnance Datum (AOD) at around 6m below ground level. Closed-to-slightly open stained joints and beds of 250 mm average thickness, along with systems of micro-fissures, provide pathways for air above the water table and water below it.

Monotonic and cyclic behaviour of SNW chalk

Vinck et al. (2022) describe the intensive characterisation conducted for ALPACA through in-situ profiling and laboratory testing on high quality block and Geobore-S rotary samples. Liu et al. (2023) report additional triaxial tests involving effective cell pressures up to 12.8 MPa that modelled the conditions beneath the pile tips during driving and compression load testing, where local mean effective stresses as high as 10MPa can develop; Jardine et al (2023). The intact chalk starts to de-structure beneath the advancing tips and soft putty forms around the pile shafts in annuli which have similar thicknesses to the pile walls. The de-structured annuli reconsolidate after driving and Jardine et al. (2023) conclude that their properties and states control the aged piles' axial resistances. Liu et al. (2022) report monotonic and cyclic triaxial tests on de-structured chalk that matched the putty conditions, showing that its behaviour is silt-like. The de-structured putty shows modest cyclic resistances that are governed by the applied consolidation stresses. Its cyclic failure involves sharp pore pressure build-up, leftward drifting of the effective stress paths, cyclic stiffness losses and growing damping ratios. Liu et al. (2022) established normalised relationships between cyclic loading parameters, mean effective stress drifts $\Delta p'/p_0'$ and strain development from their main test series on specimens consolidated (isotropically) to 200 kPa. They also noted that samples consolidated to 400 kPa developed slightly higher drift and strain rates under comparable normalised cyclic loading

levels. As discussed later, more marked leftward effective stress path drifting is anticipated under simple shear conditions, and alongside pile shafts, than is seen in triaxial tests.

The surrounding intact chalk provides stiff radial containment to the reconsolidated putty annuli formed around the pile shafts and constrains any dilation that develops as the putty fails monotonically or degrades under cycling. Ahmadi-Naghadeh et al. (2022) investigated intact SNW chalk's undrained cyclic triaxial behaviour under in-situ stress conditions. High quality samples could withstand one-way deviator stress amplitudes, $q_{cyc} = \Delta\sigma_1 - \Delta\sigma_3$, up to 700 kPa in a fully stable manner. In cases where failure developed under higher-level cycling, the intact chalk's cyclic response remained stiff, with little or no sign of pore pressure change or impending instability until shortly before abrupt brittle failure. Although chalk can be reduced to putty by high-level repetitive straining, its response to one-way, stress-controlled, cycling resembles that of rocks, concrete or metals.

Pile arrangements and instrumentation

Aiming to check for any potential effects of scale on cyclic response, ALPACA employed a wide range of pile diameters and ages after driving. Table 1 summarises the axial-cyclic subset of eight nominally identical 508mm OD open-tubular 'LD' piles driven to 10.15m tip depths, with 41% of their shaft lengths below the water table and $L_p/D \approx 20$. The piles' 20.6mm wall thicknesses (giving relatively low $D/t_w \approx 25$) were instrumented with opposing strings of optical fibre Bragg grating (FBG) strain gauges (Buckley et al., 2020b). Axial-cyclic tests were also conducted on six new 'SD series' 139mm OD piles, one of which also carried FBG gauges. These piles terminated above the water table at 5.45±0.1mbgl depths.

The test piles' average end of driving (implicitly compressive) unit shaft resistances of ≈20 to ≈32 kPa, as computed with the aid of iterative signal matching analyses, fell systematically with L_p/D due to the 'h/R' (or more loosely 'friction fatigue') processes outlined by Jardine et al (2023). All were left undisturbed for 7 to 11 months before applying any loading. Static tension 'control' tests were conducted on three further LD and SD piles to define average reference static tensile shaft capacities Q_{ref} under conditions that matched the ages of the cyclic test piles. The shaft capacities were corrected for the piles' and chalk plugs' effective self-weights. The brittle and free draining nature of the chalk eliminated any need to discount any reverse end-bearing resistances. The average tensile shaft resistance τ_{avg} versus normalised axial displacement (w/D) trends from the control piles' slow, stage-loaded, monotonic tension tests, including Buckley et al's (2018a) 'SD' case are shown in Figure 1. Differences of ±15% in shaft capacity were found between similar (relatively slow) maintained load tests on the piles, which may reflect local variations in ground profile, pile surface conditions, installation details, test ages or load step choices; Jardine et al (2023). The SD piles' higher peak τ_{avg} and w/D ratios at failure reflect the higher degrees of set-up Λ that developed above the water table through air-enhanced corrosion processes. The average unit shaft resistance measured

in a parallel compression test on an LD pile was $\approx$2.1 that in tension, which in turn was $\approx$1.9 times the 20 kPa default CIRIA design recommendation given by Lord et al. (2002).

Cyclic testing sequence

Axial cyclic loading was applied 224 to 256 days after driving for the LD piles and after 327 and 332 days for the SD cases. One-way tension cyclic loading (A1W) tests reacted against steel and timber foundation pads. Two-way (A2W) tests, that applied both compression and tension loads, reacted against kentledge and adjacent piles respectively in the SD and LD tests. None of the tests applied a significantly compressive mean load. Four displacement transducers placed equally around the pile axes measured axial movements relative to reference frames fixed to sufficiently distant datum points. Strain gauged load cells measured the constant-amplitude sinusoidal loading applied through automated hydraulic systems at $\approx$0.1Hz, the frequency routinely adopted to match offshore wave loading (e.g Lombardi et al 2017).

The tests applied sinusoidal load cycles, as defined in Tables 2-3, where Q_{cyc} is the (half peak-to-trough) load amplitude and Q_{mean} the mid-cycle value. Both are normalised by the listed Q_{ref} values from the monotonic tension tests. Cycling continued until either failure occurred after N_f cycles, or the pre-programmed (typically 1,000 to 2,000 cycle) test durations were reached without any failure. One test extended to 10,000 cycles to check longer-term trends. All started with an initial batch of cycles that was designed to avoid failure. Around half the piles were subjected to a distinctly higher-level second cyclic batch after allowing a short pause. For the LD tests, these pauses typically extended for the 20 to 40 minutes required to re-set the loading system, while only three to five minutes delays were required for the SD piles. The potential impact of stable initial cyclic loading on any far higher level second batch was assumed negligible. Final stage loaded axial static tension (AST) tests to failure were conducted on all piles, typically within around 2 hours of their final cycle. Working day limitations led to shorter maintained load 'creep' stages being imposed than in the reference tests. Loads, displacements and FBG strains were recorded throughout each cycle of loading; a logging malfunction led to displacement data being lost over the first 1,000 cycles of test S20.

Failure and stability criteria

As outlined below, the cyclic test outcomes fell into three categories following a scheme modified slightly from those employed previously (Karlsrud et al., 1986; Poulos, 1988; Jardine & Standing, 2000; Buckley et al., 2018a). The same normalised criteria were applied to the LD and SD tests and, as all displacements were vertically upwards, the pile loads are normalised by the tension shaft capacity applying prior to cycling.

Unstable (US): Failure occurs within 1,000 cycles after marked reductions in shaft capacity and pile loading stiffness k_L. The axial movements required to reach failure in slow monotonic maintained tension load tests were relatively small (0.02 to 0.04D) for most ALPACA piles (Jardine et al 2022). Noting that generally smaller displacements could be expected in faster 0.1Hz cyclic tests, the onset of cyclic failure was defined as the point where either the accumulated peak displacement $\boldsymbol{a}$, reached $0.02D$ or the peak-to-trough displacements d_a, exceeded $0.01D$, as defined, with cyclic stiffness, in Figure 2. The accumulated peak displacement criterion was usually the most critical, although peak-to-trough movements became more important in tests with low mean loads and high cyclic amplitudes.

Stable (S): Shaft capacity does not degrade significantly and accumulated total displacements remain negligibly small over at least 1,000 cycles. 'Negligible' is taken here to mean no more than $1/10^{th}$ of the accumulated peak and peak-to-trough displacements associated with failure, or $0.002D$ and $0.001D$ respectively. Stable cycling can lead to tension capacities increasing marginally while peak-to-trough movements can reduce leading to increasing pile stiffnesses.

Metastable (MS): Cases that fall between these limits. Piles do not fail within 1,000 cycles, but accumulated displacements may exceed $0.002D$ and/or peak-to-trough displacements exceed $0.001D$. Tension capacity and pile stiffness reductions may occur, but insufficiently for the failure criteria to be met within 1000 cycles.

It is often acceptable in practice to design a foundation to sustain limited numbers of metastable loading cycles, provided that appropriate factors are applied to ensure that the piles satisfy the safety and serviceability criteria applying under the site-specific cyclic design conditions, see for example Jardine et al (2012).

Adopting displacement-based criteria in addition to those related to axial capacity trends allowed the test outcomes to be categorised, including 'first-stage' tests that did not conclude with tension loading to failure. Naturally, applying different criteria to those outlined above could lead to individual tests falling into different categories.

RESULTS & INTERPRETATION

The cyclic tests' loading conditions are plotted in Figure 3 in normalised interaction diagrams that also indicate the total number of cycles, N, applied. As noted earlier, the undisturbed tension capacities of individual cyclic test piles may differ from the reference values and the true test coordinates could vary up to ±15% from those plotted. Corrosion processes were identified by Jardine et al (2022) as being important to pile capacity gains over time (or 'set-up') at SNW and responsible

for higher pre-loading local radial (σ_{rc}') stresses applying in the de-structured chalk around their shafts, as well as potentially boosting the 'constrained dilation' $\Delta\sigma_{rd}'$ increases that have been proven to develop on loading in chalk (Buckley et al 2018b). Their contribution to overall shaft capacity is known to vary inversely with pile diameter (Jardine et al 2018).

All the pile tests involved upward movement trends and those annotated as F underwent tension shaft failures after N_f cycles. The top-left to right-bottom diagonals represent lines of static Factor of Safety, FoS = Q_{ref}/Q_{max}. Tentative N_f = 10, 100 and 1,000 contours are plotted to indicate the normalised cyclic load combinations under which the specified numbers of cycles are required to reach failure. All contours must converge to Q_{cyc}/Q_{ref} = 0 when Q_{mean}/Q_{ref} =1, the point which represents monotonic failure. By definition, all loading conditions plotting above the N_f = 1,000 contours should be unstable (US) and those below are either metastable (MS) or stable (S). However, the implicit ±15% scatter in monotonic capacity and the potential impacts of variations in individual testing conditions made it difficult to find contours that fit all outcomes fully satisfactorily. The safety implications of under-estimating cyclic impact led to choosing contours on marginally 'conservative', rather than best fit, basis. Among the LD tests, one failed at an N value lower than implied by the nearest contour, while three that ended without failure plotted 'conservatively' above the N=100 or N=1000 failure contours. The SD series included two tests that failed at N values lower than implied by their nearest contour failure contours, while five un-failed tests plot 'conservatively' on or above the N=100 or N=1000 contours. The scales of the outlying SD and LD tests' deviations from the expected overall contour system were generally less than ±0.1 Q_{ref}.

The LD tests' contours shown in Figure 3 (a) plot, on their right-hand sides, up to 0.12 above their SD equivalents in Figure 3 (b). As noted earlier, the SD piles developed ≈80% higher 'aged' unit shaft resistances, mainly due to corrosion-linked processes being more active above the water table. SD piles could only survive 1,000 one-way cycles (imposing Q_{mean} = Q_{ref}) when the ratio of monotonic shaft capacity to maximum cyclic load (or FoS) exceeded ≈1.6, while the LD piles survived all one-way cycling. Model tests reported by Tsuha et al. (2012) show that the 'constrained dilation' $\Delta\sigma_{rd}'$ radial stress component is less effective in resisting cyclic loading in sand, so the lower cycling resistance of the SD piles may reflect an associated effect of scale. The contours confirm that far higher 'static' FoS values are required to survive extreme two-way cycling than under any one-way condition: SD piles could only survive 1,000 symmetrical two-way cycles (with Q_{mean}/Q_{ref} ≈ 0) if FoS >3.6, while the equivalent LD tests remained un-failed when FoS >2.9. Comparable FoS limits were interpreted from cyclic tests on 457mm OD steel pipe piles driven in dense sand at Dunkirk, France; Jardine & Standing (2012).

Impact on overall and local shaft tension capacity

The ALPACA tests' ratios of post cyclic capacity, Q_{pc}, to monotonic reference tension capacity are listed in Tables 2-3. Allowing for test pile variability, the "unfailed" stable cases (Tests 5, 10A, 11) suffered little or no degradation. Their average Q_{pc}/Q_{ref} ratio (1.25) indicates capacity gains, as noted in Dunkirk sand by Jardine & Standing (2012). Metastable loading (in Tests 6, 12A and S25A) led to marginal degradation and an average of 0.93. The Unstable piles' ratios ranged from 0.39 to 0.87, with an average ≈0.63. Failure occurs when shaft capacities degrade to match the applied Q_{max}. The unstable piles' post-test capacities scattered around an average $Q_{pc}/Q_{max} ≈ 1.07$, possibly reflecting marginal recovery over the ≈2 hours that typically elapsed between the final cycle and reaching peak capacity stages of check tests.

Further insights are given into shaft capacity degradation by the dual strings of FBG strain gauges installed on all LD piles. Careful analysis and filtering allowed axial pile load-depth profiles to be established for all test stages. Differentiation with respect to depth identified the shaft shear stresses transferred to the chalk. Any degradation under cycling can be identified by comparing the limiting tension profiles from the (i) the End-of-Driving (EoD) profiles established from back analysis of fully instrumented dynamic tests, tentatively divided by 2 to predict EoD tension resistance, (ii) the 'aged reference' tension test, (iii) peak tension loading over the second ($N = 2$) cycle and (iv) the post-cyclic monotonic tension test conducted after the batch of cycling.

The profiles for Test 11, which was fully stable over 10,000 cycles are presented in Figure 4(a). The $N = 2$ peak cyclic loading profile remained largely below the reference static test curve and the post-cycling profile confirms marginal capacity enhancement. However, unstable cases, such as Tests 8A and 13A illustrated in Figure 4(b-c), manifested markedly reduced shaft capacity from the reference static test curve after 21 and 69 cycles respectively. In both cases degradation was greatest over the lowest shaft sections where the reference static resistances were highest because the de-structuration that occurs during driving increases systematically with normalised distance (h/R) above the pile tip; Buckley et al. (2018a) and Jardine et al. (2018), (2023). Comparison with the EoD profiles (corrected to tension resistances) reported by Jardine et al (2023) shows that cycling to failure reduces local resistances at points within 1 to 2m of the pile tip to below the EoD values but induces less damage higher on the shaft. The uppermost 2m, where access to air accelerated corrosion and set-up, was also degraded markedly in Test 08A. Top-down patterns of cyclic degradation are more common with other geomaterials (see Erbrich et al., 2010 or Jardine et al., 2012). The LD and SD piles had relatively high axial stiffness due to their relatively low D/t_w ratios; a more top-down degradation pattern might apply to piles driven with higher D/t_w or L/D ratios.

Styles of load-displacement response

The tests' load-displacement responses reflect their degrees of cyclic stability. The long-term stable Test 11, illustrated in Figure 5 developed just 1mm of accumulated peak displacement over 10,000 cycles, while the unstable loading applied to a similar pile in Test 8A developed large movements as it progressed to fail within 11 cycles. Figures 6-8 plot the normalised absolute and double-amplitude displacement accumulation trends with the number of cycles *N* for all tests, grouping the unstable (US), metastable (MS) and stable (S) cases into sub-sets. The US tests displayed the most variation, with some failing over their first few cycles, while others accumulated displacements more slowly. Some showed marked upward inflections towards abrupt failures, while others crept towards gentle failures over several hundred cycles.

The MS category showed more systematic trends with the double amplitude displacements, and the rates of total displacement accumulation, declining systematically with *N*. Finally, the stable (S) tests showed only modest displacement accumulation over their first few hundred cycles, as observed by Buckley et al. (2018a).

Trends in accumulation of cyclic displacement

It is argued in Appendix A that any accumulated peak cyclic pile head displacements are dominantly generated by plastic shear straining within the annular zone of putty chalk that forms around the pile during driving. Noting that the widths of the putty zones are practically equal to the pile wall thickness t_w (see Buckley et al. 2020) the absolute magnitudes of the accumulated peak pile head displacements, a, are expected to scale linearly with t_w when all loading factors are held constant. Logarithmic plots of the stable and metastable tests' absolute cyclic displacements (defined in Figure 2) trends reveal power law trends with N of the form:a

$$\frac{a}{t_w}(\%) = \frac{D}{t_w}\alpha N^\beta \qquad (1)$$

where α and β are non-dimensional fitting parameters that vary with the normalised cyclic loading levels. Figure 9 shows examples of the fitted power law trends for the MS and S classification tests, while Table 4 gives the best fitting α and β values for individual tests.

Equations (2) and (3) were developed to relate α and β more generally to the normalised cyclic loading parameters through a global fitting approach that gave the least average absolute differences between the measured and predicted cyclic displacements developed after 10, 100 and 1000 cycles across the full set of metastable and stable tests on SD and LD piles, giving the average errors listed in Table 4. Parameter α was found to be largely independent of the cyclic loading ratio (Q_{cyc}/Q_{ref}), while parameter β was insensitive to the mean load level (Q_{mean}/Q_{ref}). However, as with the cyclic failure contour plots discussed above, scatter between test outcomes made it difficult to fit all tests satisfactorily. The overall best-fitting global expressions (Equations 2 and 3) gave 'good' fits to about 30% of cases, 'acceptable' matches to 50% and 'poor' fits to the remaining 20%.

$$\alpha = \frac{t_w}{D} \times (0.95 \times \frac{Q_{\text{mean}}}{Q_{\text{ref}}} + 0.0025) \text{ (in \%)} \qquad (2)$$

$$\beta = 1.73 \times \frac{Q_{\text{cyc}}}{Q_{\text{ref}}} \qquad (3)$$

Figure 10 (a) presents examples of two 'good' fits while Figure 10 (b) shows two 'poor' examples. These latter cases' variations from expected behaviour may be related to unknown variations in the piles' monotonic reference capacities and the cyclic test outcomes' sensitivity to the normalised cyclic loading parameters.

Axial cyclic stiffness trends

The cyclic tests' double amplitude displacements led to global cyclic pile stiffnesses, k_L as defined in Figure 2 which reduced systematically with cyclic load amplitude and evolved as cycling progressed. Figures 11-12 present the stiffness trends, grouped by stability classification. The unstable tests generally showed clear, marked, stiffness reductions from the onset of cycling up to failure. However, two SD tests, S22 and S27A, that plot along the FOS=1.5 line in Figure 3, accumulated peak displacements more slowly than other unstable tests (see Figure 6) and manifested relatively stable stiffness trends up to the onset of failure.

The metastable LD tests also tended to show significant reductions from the onset of cycling while their SD equivalents indicated relatively stable, slightly increasing stiffness. The stable LD tests showed steady, or increasing, stiffnesses trends.

The maximum k_L values observed in the cyclic tests were $\approx 6.0 \times 10^5$ kN/m and $\approx 3.0 \times 10^6$ kN/m for the SD and LD piles respectively, after excluding the erratic trace from Test 10. Jardine et al. (2022) report similar initial k values ($\approx 6.0 \times 10^5$ kN/m and $\approx 2.0 \times 10^6$ kN/m) from the earliest (near linear) stages of the equivalent monotonic reference tests. These stages were analysed applying closed-form elastic solutions developed by the authors, through an extension of Randolph and Wroth's (1978) methodology, to account for the LD and SD piles' geometries, axial compressibility and zero-base load under tension loading. Maximum elastic chalk vertical shear stiffnesses G_{vh} of 310 to 450 MPa were interpreted from the SD and LD pile tests, which correspond, on average, to $\approx 25\%$ of the average G_{vh} average from nearby Seismic CPT profiling; see Vinck et al. (2022). Jardine et al. (2022) ascribe this feature to the chalk's natural fissuring and the damage inflicted by pile driving, including the formation of the putty annuli.

MODELLING OF CYCLIC SHAFT FAILURE CONDITIONS

Model calibration chamber experiments involving highly instrumented mini-ICP piles installed in pressurised sand masses reveal that their cyclic shaft capacity degradation involves radial effective stresses reducing under the highly kinematically constrained, near constant volume, conditions applying at the soil-pile interface (Tsuha et al., 2012). Cyclic triaxial, Simple Shear or Hollow Cylinder Apparatus (HCA) laboratory tests indicate how effective stresses may reduce, permanent

strains grow and stiffnesses fall as functions of the applied cyclic loading; see for example Aghakouchak (2015), Rattley et al. (2017) or Jardine (2020). While Constant Normal Stiffness (CNS) tests may be attempted to model the pile shaft interface boundary conditions (Erbrich et al 2010), undrained laboratory tests also provide a representative and practical approach, especially when the surrounding soil mass is as stiff as the intact chalk.

Jardine et al. (2012) outline how cyclic laboratory tests may be applied in at least three ways to help predict pile stability under cyclic loading. The most theoretically attractive and yet challenging route is to employ fully-fledged numerical analyses employing cyclic constitutive models calibrated to the laboratory experiments. A second possible path involves conducting cyclic T-z analyses in which subsections of the pile are represented by local reaction models that degrade with cycling in accordance with the cyclic laboratory tests. Such an approach was applied by Atkins (2000) to model the Dunkirk sand cyclic tests successfully, while also offering scope to capture any progressive cyclic shaft failure as explored also by Erbrich et al., (2010) and others. However, a significant difficulty in applying such modelling is the 'bottom-up' rather than 'top-down' pattern of progressive failure pattern observed in the ALPACA field tests. Alternatively, a simplified global approach may be adopted that applies the laboratory tests uniformly over the whole pile. This implicitly neglects any progressive failure and gives no direct information on total displacements or stiffness. However, Aghakouchak (2015) and Jardine (2020) show that, when combined with suitably conditioned laboratory tests, the approach led to representative predictions for the failure conditions of cyclic field pile tests conducted at Dunkirk and model pile tests in NE34 sand. Rattley et al. (2017) further describe how a related approach allowed cyclic simple shear tests to be applied in cyclic design checks for a major offshore windfarm. A similar simplified global approach is applied below to investigate the correspondence between the cyclic element testing and the cyclic failure of LD and SD piles under load-controlled field conditions.

The piles' axial capacities are controlled by the properties of, and conditions within, the reconsolidated de-structured annuli which are located around the pile shafts and constrained by the stiff intact chalk. Liu et al. (2022b) explored how mean effective stresses decline under undrained cyclic loading within the de-structured annuli. Their main triaxial programme was run on samples isotropically reconsolidated to 200 kPa with further specimens consolidated to 400 kPa. Parallel monotonic tests indicated that the putty developed pre-Phase Transformation peak shear strengths $S_u^{pre-PT} = 0.25p_0'$, so the two programmes considered conditions where the maximum shear stresses developed would be no greater than 50 and 100 kPa respectively, matching the average monotonic shaft resistances of the LD and SD piles shown in see Figure 1, although subject to the local variations with depth illustrated in Figure 4.

Predictions of the pile cyclic loading conditions at which failure would be reached after specified numbers of cycles were made from the cyclic triaxial test outcomes. Appendix A details how average degrees of shaft degradation were assessed following the procedures of Aghakouchak (2015) and Jardine (2020), adopting an interface failure angle $\delta_f' = 32^o$ after ring shear tests by Vinck (2021) on de-structured chalk. The results are summarised in Figure 14 by comparing the predicted 'global' contours for failures with $N_f = 10$, 100 and 1,000 with the 'consciously conservative' contours taken from Figure 3. The LD field test contours and those predicted from the $p_0' = 200$ kPa triaxial tests follow broadly similar tends, although the latter overpredict the Q_{cyc}/Q_{ref} ratios at which cyclic failure occurs at given N_f values, with the largest difference (0.1) applying to the $N = 10$ contour covering extreme two-way cycling, while the Q_{cyc}/Q_{ref} contours for $N = 1,000$ agree within 0.03. This may reflect the conservative interpretation of the field tests, the progressive failure that occurs from the pile tip upwards (see Figure 4(b-c)) or other simplifying assumptions made in the analysis. The SD field contours are compared in Figure 14 (b) with predictions made from the more cyclically susceptible $p_0' = 400$ kPa triaxial tests that best match the SD piles' average shaft radial effective stresses. Here too broadly similar patterns were obtained with $A = -0.05$ and $B = -0.05$, where A and B are fitting parameters for the effective stress degradation (see Appendix A), although the predicted contours plot up to 0.15 Q_{ref} above the conservative trends interpreted from the pile load tests. As discussed in the Appendix and demonstrated in Figure 15 the prediction for the smaller diameter SD piles may be more affected by the simplifying assumptions made regarding the influence of the constrained dilation component of monotonic shaft resistance, which varies inversely with pile diameter. While further refinement is possible, the calculations provide broadly representative predictions that both aid test interpretation and offer a simplified procedure that can aid practical cyclic foundation design.

CONCLUSIONS

Monotonic tests on open-steel pipe piles driven in low-to-medium density chalk for the ALPACA research programme developed monotonic shaft resistances that varied with pile diameter, L/D ratio, age after driving, relative water table depth and loading sense (compression-versus-tension). Comprehensive axial cyclic testing programmes conducted on fourteen aged and otherwise undisturbed SD and LD piles led to ten primary conclusions:

1. The field test outcomes yield systematic patterns in normalised cyclic interaction diagrams that allow contoured representation of the conditions under which either cyclic failure develops under specified numbers of cycles, or stable and metastable conditions apply.

2. The cyclic shaft resistances of the test piles were controlled by the behaviour of, and conditions within, the reconsolidated, de-structured, chalk putty annuli that form around the pile shafts during driving and are constrained radially by the stiff intact chalk mass.

3. Cyclic axial loading degraded shaft resistance most severely under high-level, two-way, loading involving low mean loads. This feature may be critical to cyclic foundation design.

4. SD piles were more susceptible, in normalised terms, to severe cyclic loading than LD piles. A Factor of Safety ≈2.9 was required for LD piles to survive 1,000 cycles under extreme two-way conditions, while a Factor ≈3.6 appeared necessary for SD piles.

5. FBG strain gauge strings identified the patterns of degradation applying in unstable tests as involving progressive failure from the pile tip upwards.

6. Post-cycling monotonic tests to failure confirmed that stable cycling enhances pile capacity marginally, while unstable cases may experience large losses of shaft capacity. Metastable intermediate outcomes involved only minor shaft capacity losses.

7. The patterns by which pile head deflections grew under cyclic loading varied systematically with the normalised axial loading parameters and could be captured by simple fitting expressions.

8. The non-linear pile cyclic stiffnesses varied with loading conditions in a consistent fashion. Checks with elastic theory demonstrated that the highest operational shear stiffnesses that could be interpreted for the chalk mass amounted to approximately 25% of those measured by in-situ Seismic CPT tests. This trend was ascribed to the Chalk's fissured macro-structure and damage caused by pile driving.

9. Cyclic triaxial tests conducted on chalk putty samples consolidated to conditions comparable to the average states applying around the test piles gave fair 'global' predictions for the pile test failure conditions when combined with laboratory interface shear test outcomes.

10. A trend was noted for the global predictions to be marginally non-conservative, which may be related to unmodelled phenomena such as the piles' top upwards progressive failures. However, the simplified treatment followed appeared to capture the main processes that lead to shaft capacity degradation under cyclic loading.

APPENDIX A

A schematic illustration of the local stress paths expected on the pile shaft under monotonic and cyclic loading to failure is given in Figure 14. Buckley et al. (2018b) show that the shaft shear stress τ_{max} static at which driven piles reach failure in chalk satisfy the Coulomb failure criterion.

$$(\tau_{rzf}^{max})_{static} = \sigma_{rf}' \, tan(\delta_f') \quad \text{(A1)}$$

The radial effective stress acting on pile shafts under monotonic failure, σ_{rf}', in Equation A1 is determined by installation and ageing, prior to static loading which define σ_{rc}' plus any reduction induced during static loading ($\Delta\sigma_{rd}'$) by principal stress axis rotation and the increases that occur due to constrained dilation, which vary inversely with pile diameter.

$$(\sigma_{rf}')_{static} = \sigma_{rc}' + \Delta\sigma_{rd}' \quad \text{(A2)}$$

$$S = \frac{(\sigma_{rf}')_{static}}{\sigma_{rc}'} = \frac{(\tau_{rzf}^{max})_{static}}{\sigma_{rc}' \times tan(\delta_{f}')} \quad \text{(A3)}$$

Under cyclic loading conditions, local shaft cyclic failure initiates when the peak of the cyclic effective stress paths engage the interface failure δ_f' envelope (Tsuha et al., 2012), neglecting the impact of pre-shear on σ_r' under cyclic loading.

$$tan(\delta_f') = \frac{(\tau_{rz}^{max})_{cyclic}/\sigma_{rc}'}{(\sigma_r')_{cyclic}/\sigma_{rc}'} \quad \text{(A4)}$$

$$\left[\frac{\sigma_{rf}'}{\sigma_{rc}'}\right] = \frac{\tau_{rz}^{max}/\sigma_{rc}'}{tan(\delta_{f}')} \quad \text{(A5)}$$

$$\left[\frac{\Delta\sigma_{rc}'}{\sigma_{rc}'}\right] = 1 - \frac{\tau_{rz}^{max}/\sigma_{rc}'}{tan(\delta_{f}')} \quad \text{(A6)}$$

Cyclic failure is initiated when the stress path engages the interface shear failure criterion, while the static failure can involve a dilatant stage in sands (Tsuha et al. 2012). Considering constant-amplitude uniform cycling conditions, the cyclic shear stress at peak τ_{max} ($= \tau_{mean} + \tau_{cyc}$) can be linked with changes in radial effective stress at cyclic failure, $(\Delta\sigma_{rc}')_{cyclic}$, through the following equation.

$$\left(\frac{\Delta\sigma_{rc}'}{\sigma_{rc}'}\right)_{cyclic} = \frac{\sigma_{rc}' - \sigma_{rf}'}{\sigma_{rc}'} = 1 - \frac{\tau_{mean} + \tau_{cyc}}{\sigma_{rc}' \times tan(\delta_{f}')} \quad \text{(A7)}$$

Combining Equations (A3) and (A7) leads to

$$\left(\frac{\Delta\sigma_{rc}'}{\sigma_{rc}'}\right)_{cyclic} = 1 - S \times \left[\frac{\tau_{mean}}{(\tau_{rzf}^{max})_{static}} + \frac{\tau_{cyc}}{(\tau_{rzf}^{max})_{static}}\right] \quad \text{(A8)}$$

Which can be rearranged as:

$$\frac{\tau_{mean}}{(\tau_{rzf}^{max})_{static}} = \frac{1}{S}\left(1 - (\frac{\Delta\sigma_{rc}'}{\sigma_{rc}'})_{cyclic}\right) - \frac{\tau_{cyc}}{(\tau_{rzf}^{max})_{static}} \quad \text{(A9)}$$

Under laboratory cyclic simple shear conditions, the horizontal plane on which cyclic shear stresses are applied is analogous to the vertical soil-pile interface surface and the laboratory axial (vertical) effective stresses acting on the horizontal plane represent the radial effective stresses on the vertical pile shaft; Aghakouchak (2015).

$$\left(\frac{\Delta\sigma_z'}{\sigma_{z0}'}\right)_{Lab\ SS} = \left(\frac{\Delta\sigma_{rc}'}{\sigma_{rc}'}\right)_{Pile} \qquad (A10)$$

Degradation in radial effective stress component ($\Delta\sigma_{rc}'/\sigma_{rc}'$) under cyclic loading can be gauged directly from the evolving trend of vertical effective stress component (σ_z') in cyclic simple shear tests (CSS). When cyclic triaxial tests are employed to match 'simple shear' pile interface conditions, the pile shaft shear stress can be related to the triaxial deviatoric stress changes (Δq) and the variations in triaxial mean effective stress ($\Delta p'$) taken as indicators as to how σ_{rc}' may change close to pile under cyclic loading. A correction factor T is introduced to correlate changes in mean effective stress under triaxial conditions and vertical effective stress under simple shear condition.

$$\frac{\Delta p'}{p_0'} = \frac{\Delta\sigma_z'}{\sigma_{z0}'} \times T \qquad (A11)$$

Figure 16 compares pairs of normalised effective stress paths from (i) monotonic triaxial tests by Liu et al. (2022) and (ii) direct simple shear (DSS) tests on normally consolidated fully de-structured chalk prepared with dynamic compaction to similar void ratios ($\approx$0.69). T falls between 0.50-0.64 at the monotonic PT points and the average $T = 0.57$ was adopted for this study. A higher T range (0.92$\pm$0.08) was identified by Aghakouchak (2015) from cyclic hollow cylinder simple shear (HCA SS) and triaxial tests on fine dense anisotropically over-consolidated Dunkirk and Fontainebleau NE34 sand.

Combining Equations (A9) and (A11) leads to

$$\frac{q_{mean}/2}{(\tau_{rzf}^{max})_{static}} = \frac{1}{S}\left(1 + \frac{\Delta p'}{p_0'} \times \frac{1}{T}\right) - \frac{q_{cyc}/2}{(\tau_{rzf}^{max})_{static}} \qquad (A12)$$

in which $\Delta p' = p' - p_0'$. Liu et al. (2022) report correlations between the changes in p' and the cyclic loading stress components (q_{mean} and q_{cyc}) as:

$$\frac{\Delta p'}{p_0'} = A \times \left(B + \frac{q_{cyc}}{p_0'}\right) \times N^C \qquad (A13)$$

$$C = 3.48 \times \frac{q_{cyc}}{p_0'} \qquad (A14)$$

Tests conducted after consolidation to $p_0' = 200$ kPa indicated $A = -0.05$, $B = -0.12$, regardless of the applied q_{cyc}/p_0' ratio, although they indicated a far wider $0.3 < C < 1.3$ range than reported for dense sands or stiff clays by Aghakouchak (2015) and Rattley et al. (2017). Parallel tests on samples consolidated to $p_0' = 400$ kPa indicated $B = -0.05$ while A and C correlations remain unchanged. Equation (A9) can offer preliminary 'global' predictions from single element tests of the failure conditions of the field cyclic pile tests through:

$$\frac{Q_{mean}}{Q_{ref}} = \frac{1}{S}\left(1 + \frac{\Delta p'}{p_0'} \times \frac{1}{T}\right) - \frac{Q_{cyc}}{Q_{ref}} \qquad (A15)$$

Applying $Q_{cyc}/Q_{ref} = \tau_{cyc}/(\tau_{rzf}^{max})_{static}$ and $Q_{mean}/Q_{ref} = \tau_{mean}/(\tau_{rzf}^{max})_{static}$, where Q_{ref} denotes the reference monotonic pile shaft capacity.

The above simple model gives potentially anomalous results in cases involving a high near-failure Q_{mean} in combination with low Q_{cyc} when if $S \neq 1$ although few tests were conducted in this region which would normally be avoided in design. The constrained dilation component led to $S > 1$ in 102mm OD ICP tests in SNW chalk by Buckley et al. (2018b), due mainly to the pile's small diameter and the chalk's high in-situ stiffness. In such cases the simplified model can imply improbably significant differences between monotonic and cyclic shaft capacities at failure. For simplicity, S was therefore taken as unity in the present study.

S27 A	SD01-A1W	162	107	39	0.45	0.21	0.66	1002	471	US	0.87

Actual applied load accounted for weight of steel and chalk plug; 1000 unlogged cycles applied prior to test S20; Loads not achieved consistently in test S23 - results not used.

Table 4 Cyclic loading parameters in stable/metastable tests

Test	Pile-type	α (%)	β	R^2	Class
5	LD11-A1W	0.0151	0.277	0.87	S
6	LD02-A1W	0.0091	0.538	1.00	MS
7[1]	LD10-A2W	-	-	-	-
8	LD08-A1W	0.0167	0.229	0.94	S
10	LD03-A1W	0.003	0.371	0.95	S
11	LD04-A1W	0.0183	0.248	0.92	S
12	LD01-A1W	0.0076	0.260	0.93	S
12A	LD01-A2W	0.0001	1.026	0.96	MS
13	LD09-A1W	0.0429	0.280	0.84	MS
S25	SD02-A1W	0.0449	0.296	0.93	MS
S25A	SD02-A1W	0.0154	0.58	0.94	MS
S27	SD01-A1W	0.0354	0.38	0.99	MS

Actual absolute displacement <0.003%D.

Table 5 Average absolute differences between measured and predicted a/D (in %) at three N levels from dataset

N	N = 10	N = 100	N = 1000
abs((a/D)$_{pre}$ - (a/D)$_{msd}$)	0.0194	0.0565	0.1194

Figure captions

Figure 1 Trends for average tensile shaft resistance for the reference LD and SD pile tests

Figure 2 Schematic illustration cyclic displacement and stiffness parameters

Figure 3 Cyclic loading interaction diagrams with numbers of cycles to the end of the test or failure: (a) LD tests; (b) SD tests from this study and from Buckley et al. (2018)

Figure 4 (a) Local shaft shear stresses evaluated from peak tension loading stage of stable Test 11 A1W, at the beginning of cycling (N = 2), after 10,000 cycles and post-cyclic tension loading to failure. Profiles of shaft resistance at end-of-driving and static tension failure averaged from the two reference tests are also shown, divided by 2 to indicate EoD tension resistances. (b) Local shaft shear stresses evaluated from peak tension loading stage of unstable Test 8A A2W, at the beginning (N = 2) and end (N = 21) of cycling, and post-cyclic tension loading to failure. Profiles of shaft resistance at end-of-driving and static tension failure averaged from the two reference tests are also shown divided by 2 to indicate EoD tension resistances. (c) Local shaft shear stresses evaluated from peak tension loading stage of unstable Test 13A A2W, at the beginning (N = 2) and end (N = 69) of cycling, and post-cyclic tension loading to failure. Profiles of shaft resistance at end-of-driving and static tension failure averaged from the two reference tests are also shown, divided by 2 to indicate EoD tension resistances

Figure 5 Example load displacement response during: (a) stable extended cycle A1W test 11 on LD04; (b) unstable A2W test 8A on LD08

Figure 6 Normalised displacement accumulation trends with cycling in unstable tests: (a) absolute displacement; (b) double amplitude displacement

Figure 7 Normalised displacement accumulation trends with cycling in metastable tests: (a) absolute displacement; (b) double amplitude displacement

Figure 8 Normalised displacement accumulation trends with cycling in stable/metastable tests: (a) absolute displacement; (b) double amplitude displacement. S20 not shown due to missed cycles

Figure 9 Example power law fits to cyclic displacement trends: (a) good fits; (b) poor fits

Figure 10 Global prediction of absolute displacement trends calculated using Eq1 to 3 (a) example of good fits (b) example of poor fits

Figure 11 Loading stiffness trends in unstable tests: (a) LD tests; (b) SD tests

Figure 12 Loading stiffness trends in metastable tests: (a) LD tests; (b) SD tests

Figure 13 Loading stiffness trends in stable tests

Figure 14 Predictions for failure contours of: (a) LD piles; (b) SD piles, as set out in Appendix A compared with field test outcomes from Figure 3

Figure 15 Schematic diagram of pile shaft failure under monotonic and cyclic loading
