We discovered a hybrid *Leishmania* parasite in Costa Rica that is genetically similar to hybrids from Panama. Genome analyses demonstrated the hybrid is triploid and identified *L. braziliensis* and *L. guyanensis*–related strains as parents. Our findings highlight the existence of poorly sampled *Leishmania* (*Viannia*) variants infectious to humans.

*L*eishmania are intracellular protozoan parasites that cause the vectorborne disease leishmaniasis, which occurs in ≈88 countries (*1*). Human infection can result in 2 main forms of disease, cutaneous and visceral leishmaniasis, and different *Leishmania* species cause diverse clinical manifestations and sequelae (*1*). Correct species typing is thus required to clinically manage leishmaniasis (*2*).

In August 2020, a patient returning from Costa Rica sought care at the Hospital St. Pierre (Brussels, Belgium) with a single, well-demarcated, ulcerated erythematous plaque on the left flank indicative of cutaneous leishmaniasis. Molecular diagnosis confirmed the presence of *Leishmania* parasites on the basis of 18S ribosomal DNA (*3*). A 1,245-bp fragment of the multicopy heat-shock protein 70 gene (*hsp70*) was sequenced for species typing (*4*). This sequencing revealed an atypical sequence related to both the *L. guyanensis* and *L. braziliensis* species that showed sequence variation across copies at 10 positions, suggesting either a mixed infection or hybrid parasite. Despite the atypical nature of the infecting species, the patient had good therapeutic

response after 5 intralesional injections with meglumine antimoniate (Glucantime, Sanofi, https://www.sanofi.com), leaving only a slightly hyperpigmented scar. The clinical sample was cultured in vitro (referred to as MHOM/CR/2020/StPierre) and subjected to HSP70 typing (*4*) and whole-genome sequencing (*5*).

Compared with results for the clinical sample, the consensus sequence of the *hsp70* locus in the cultured isolate revealed sequence variation in 1 extra site, bringing the total to 11 (Appendix 1, https://wwwnc.cdc.gov/EID/article/29/5/22-1456-App1.pdf). Of those sites, 10 were shared with 6 cutaneous leishmaniasis strains described from Panama (*6*). Comparison with all available *Leishmania hsp70* sequences from GenBank (Appendix 1) revealed 2 monophyletic groups as the possible origin of the different *hsp70* copies in the Costa Rica sequence: first, a subgroup of the *L. guyanensis* species complex found in Ecuador, Panama, and Colombia; and second, a subgroup of the *L. braziliensis* species complex described from Panama, Guatemala, and Brazil. Even though such analysis is biased by available sequences and the use of a single chromosomal locus, the geography of the hypothetical parents is compatible with Costa Rica. To further investigate the nature of the Costa Rica isolate, we resorted to genome analysis.

We identified 125,632 single-nucleotide polymorphisms (SNPs) within the sample from Costa Rica after mapping genomic sequences against the *L. braziliensis* M2904 reference genome (*5*) (Appendix 2, https://wwwnc.cdc.gov/EID/article/29/5/22-1456-App2.pdf). This total included 21,168 homozygous SNPs (both haplotypes were different from M2904) and 104,464 heterozygous SNPs (one haplotype was similar to M2904 and the other different). Chromosomes 1 and 11, the first 140 kb of chromosome 20, and the last 60 kb of chromosome 27 were highly homozygous, almost completely lacking in heterozygous variants, whereas most variants in the rest of the genome were heterozygous (Appendix 2). This observation of a largely heterozygous genome that is interrupted by homozygous stretches strongly suggests that the isolate is a hybrid parasite, rather than the result of a mixed infection (*7*).

We investigated chromosome copy numbers by using the distribution of allelic read depth frequencies at heterozygous sites (*7*), which should be centered around 0.5 in diploid organisms (both alleles represented equally). However, we discovered a bimodal distribution with modes 0.33 and 0.67 (Appendix 2), suggesting that the hybrid is triploid (*7*).

We analyzed the genomic ancestry of the hybrid compared with 40 genomes of 7 *Leishmania* (*Viannia*) species (Appendix 2) using phylogenies based on ge-
Figure. Midpoint rooted maximum-likelihood phylogenetic trees based on single-nucleotide polymorphisms called in chromosome 1 and the first 140kb of the telomeric region of chromosome 20 of a hybrid *Leishmania* parasite from Costa Rica. For each strain, sequences were composed based on concatenated single-nucleotide polymorphisms that were each coded by 2 base pairs, after which invariant sites were removed, resulting in 2,382 bp sequences for chromosome 1 and 3,015 bp sequences for chromosome 20. Consensus phylogenetic trees were generated from 1,000 bootstrap trees using IQ-TREE (http://www.iqtree.org) with 37 taxa (excluding *L. naiffi* and *L. lainsoni* strains) under the transversion with empirical base frequencies, ascertainment bias correction, and discrete gamma with 4 rate categories substitution model, which was the best-fit model revealed by ModelFinder as implemented in IQTREE. Branch support values are presented near each node following 1,000 bootstrap replicates; bootstrap values within the clade containing *L. panamensis* strains were omitted for clarity reasons. Scale bar indicates number of substitutions per site. Appendix 2 (https://wwwnc.cdc.gov/EID/article/29/5/22-1456-App2.pdf) includes a description of the *L. braziliensis* 1–4 lineages.

nomic regions that were homozygous in the hybrid (where both haplotypes originate from the same parental species). In the chromosome 20 phylogeny, the Costa Rica hybrid clusters with *L. braziliensis* 1 strain Lb8102 from Colombia (Figure; Appendix 2 Figure 8), which could be close to one of the parental strains. The ancestry of the other parental genome remains unclear, because in the chromosome 1 phylogeny it clusters with *L. panamensis* strains from Colombia and Panama (Figure), even though it is also tightly linked with a cluster of *L. guyanensis* strains from Venezuela, Brazil, and French Guiana in the mitochondrial maxicircle phylogeny (Appendix 2 Figures 3, 9). We could not resolve the geographic origin of the 2 parents in greater detail because of the lack of available *Leishmania* (*Viannia*) genomes.

Our study provides a detailed genomic description of a hybrid between the *L. braziliensis* and the *L. guyanensis* species complexes. The first report of such hybrids in Central America dates back to the early 1990s, concerning putative *L. braziliensis*–*L. panamensis* hybrids from the north of Nicaragua (*8*). Those hybrids were reported again in 2021 in Panama (*6*). Further, parasites with signatures from both *L. braziliensis* and *L. guyanensis* relatives have been described in South America, more specifically from Ecuador, Peru, Brazil, and Venezuela (*9,10*). Together with our report from Costa Rica, these reports point to a widespread circulation in the Neotropical region of recombinant strains, the epidemiology and clinical significance of which remain elusive.

Acknowledgments

We thank Pieter Monsieurs for help with generating whole-genome sequence data and Isabel Micalessi and Lara Balcaen for molecular diagnosis of the case.

About the Author

Dr. Van den Broeck is a researcher specializing in genetics and population genomics of eukaryote parasites, particularly parasites that cause neglected tropical diseases. He has contributed multiple research papers investigating the complex hybrid ancestry of protozoan parasites, such as *Trypanosoma cruzi* (agent of Chagas disease) and *Leishmania braziliensis* (agent of cutaneous leishmaniasis).

Example of sequence electropherogram for each ambiguous position

- Sequence comparison excluding the ambiguous sites from the alignment links the isolate with the *L. guyanensis* and *L. braziliensis* species complexes.

Evolutionary relationships of taxa

The evolutionary history was inferred using the Neighbor-Joining method [1]. The optimal tree with the sum of branch length = 0,02257800 is shown. The percentage of replicate trees in which the associated taxa clustered together in the bootstrap test (2000 replicates) are shown next to the branches [2]. The tree is drawn to scale, with branch lengths in the same units as those of the evolutionary distances used to infer the phylogenetic tree. The evolutionary distances were computed using the p-distance method [3] and are in the units of the number of base differences per site. The analysis involved 34 nucleotide sequences. Codon positions included were 1st+2nd+3rd+Noncoding. **All positions containing gaps and missing data were eliminated.** There were a total of 1218 positions in the final dataset. Evolutionary analyses were conducted in MEGA7 [4].

- This indicates either a hybrid strain or mixed infection.

- To identify the parental sequences of the hybrid or the mix, all *hsp70* sequences spanning the full 1245 bp fragment from GenBank were analyzed (January 31, 2022), supplemented with patient sequences from the Institute of Tropical Medicine (Antwerp, Belgium).

- In the 11 ambiguous positions, several nucleotides were found only in a subset of *L. guyanensis* from Ecuador (further called **parent 1b**), and equally so in an unidentified group of sequences from Panama (published in Miranda *et al.* 2021) (**parent 1a**).

- If these sequences are indeed a parent, all other nucleotides in the ambiguous positions need be accounted for by the second parent, leaving only a subgroup of *L. braziliensis* as the second possible parent (called further **parent 2**).

Table: comparison of MHOM/CR/2020/StPierre with putative parental sequences at the 11 ambiguous sites. Identification of the parental sequences: please refer to legend of figure on next page. Number of identical sequences in the analysis is in brackets following sequence descriptions.

Parent2 15 L braziliensis Brazil(7) Panama(1)	G	G	A	G	T	A	C	G	T	A	C

- Not only could the hypothetical parental lines account for all 11 of the ambiguous positions, but conversely, every single one of the 1245 positions in the mix/hybrid showed the nucleotide(s) present in both parents. In other words: all sequence variation in the parents was accounted for in the hybrid/mix sequence.

- Phylogenetic analysis of these hypothetical parental sequences gave the following results:

- The putative parental haplotypes were confirmed partly by whole genome sequencing, using sequence reads covering several ambiguous sites.

- Interestingly, 7 sequences previously reported from Panama (3 of which published in Miranda *et al.* 2021) share up to 10 ambiguous positions with the Costa Rica sequence.

- The following figure shows (dash representing similarity with top sequence)

  o The ambiguous sites in the Costa Rica sequence.

  o The nucleotides in the 7 previously reported sequences from Panama (identified with GenBank entry).

Genome Analysis of Triploid Hybrid *Leishmania* Parasite from Neotropics

Appendix 2

Genome sequence analyses of MHOM/CR/2020/StPierre

PART A: Decomposing of haplotype sequences for the HSP70 gene

The ambiguity of bases at 11 positions in the HSP70 fragment (Table 1) prompted us to decompose haplotype sequences to infer the parental species of MHOM/CR/2020/StPierre. To this end, 150bp read sequences were mapped with SMALT against one of the HSP70 genes within the *L. braziliensis* M2904 reference genome. Sequence data spanning all six neighboring ambiguous positions (1576–1679) in one read were extracted. This revealed five sets of identical sequences (i.e., haplotypes) found within a total of 83 high-quality read sequences. Haplotype 1 (H1) was found in 26 read sequences (32%) and has alleles equal to the *L. braziliensis* M2904 reference (Table 1). Haplotype 2 (H2) was found in 31 read sequences (38%) and contains alleles specific to *L. guyanensis* (Table 1). The remaining 3 haplotypes (26 sequences) showed signatures of mosaic ancestry, with allelic combinations similar to haplotypes 1 and 2.

PART B: Whole genome sequence analyses

Publicly available sequence data

To capture as much as possible the genome diversity of *Leishmania (Viannia)* in South-America, we included publicly available sequence data from 35 strains and generated sequence data for 5 strains. Specifically, we included sequence data of the following seven *Leishmania (Viannia)* species: *L. lainsoni* (N = 1) (*1*), *L. naiffi* (N = 3) (*2–4*), *L. shawi* (N = 1) (*4*), *L.*

guyanensis (N = 3) (*2–5*), *L. panamensis* (N = 15) (*4,6–8*), *L. peruviana* (N = 2) (*7*) and *L. braziliensis* (N = 15) (*7,9*) (Table 2).

The three *L. guyanensis* strains originated from French Guiana, Brazil and Venezuela. The 15 *L. panamensis* strains originated from Colombia (N = 13) and Panama (N = 2) (Table 2). Note that one strain (LgCL085) was previously considered as *L. guyanensis* (*3*), but was here classified as *L. panamensis* following the phylogenomic analyses presented below.

We considered a total of four genetically divergent subgroups within the *L. braziliensis* species complex. The first subgroup, here-after referred to as *L. braziliensis* 1, is regarded as the main *L. braziliensis* species and is responsible for human (muco-)cutaneous leishmaniasis. The second subgroup, here-after referred to as *L. braziliensis* 2, has been occasionally diagnosed in Peru and Bolivia (*10–12*). The third subgroup, here-after referred to as *L. braziliensis* 3, was described within a geographically restricted ecotype in the Pernambuco state in Brazil (*13*). The fourth subgroup, here-after referred to as *L. braziliensis* 4, includes two strains from Colombia (*9*), and was classified as such by us following the phylogenomic analyses presented below.

Genome sequencing of five *L. braziliensis* strains

Sequence data was generated for three *L. braziliensis* 2 strains (CUM555, CUM663 and PER163) and two *L. braziliensis* 3 strains (HBO and LIS) (Table 2). To this end, parasites were grown in culture medium for 3 to 4 days at the Antwerp Institute of Tropical Medicine or FIOCRUZ in Brazil, and their DNA was extracted using a commercial column DNA extraction protocol. At the Wellcome Sanger Institute, genomic DNA was sheared into 400 to 600 bp fragments by focused ultrasonication (Covaris Inc.), and amplification-free Illumina libraries were prepared (*14*). One hundred base pair paired end reads were generated on the HiSeq 2000, and 150 bp paired end reads were generated on the HiSeq ×10 according to the manufacturer's standard sequencing protocol.

Bioinformatic analyses

Genomic sequence reads of all strains were mapped against the *L. braziliensis* M2904 reference genome (available on https://tritrypdb.org as LbraziliensisMHOMBR75M2904_2019) using SMALT v0.7.6 (https://www.sanger.ac.uk/tool/smalt-0/). This reference includes 35 major chromosomes (32.73Mb) and a complete mitochondrial maxicircle (27.69kb) (*7*).

Given the diversity of species included in this study, we tested the quality of sequence alignments against the M2904 reference by characterizing the accessible genome (*15*), i.e., genomic regions with a minimum read depth of 5, mapping quality of 25 and base quality of 25. The coverage of the accessible genome ranged between 28.6Mb (87.2% of the chromosomal region) for *L. shawi* strain M8408 and 30.4Mb (92.9%) for *L. braziliensis* strain Lb8025 (Table 3). The coverage for strain MHOM/CR/2020/StPierre was equal to 30.0 Mb (91.8%) (Table 3). These results showed that a substantial fraction of the reference genome can be used for genotyping and ancestry analyses.

Large number of heterozygous sites (where one haplotype is similar to M2904) points to a member of the *L. braziliensis* species complex as one of the parents

A total of 125,632 SNPs were identified within the strain from Costa Rica, including 21,168 homozygous SNPs (where both haplotypes were different to the consensus sequence of M2904) and 104,464 heterozygous SNPs (where one haplotype was similar to M2904 and the other different). This latter observation indicates <u>*L. braziliensis* as one of the species</u> that contributed sequences. This number of heterozygous SNPs was at least 4.1 and 16.4 times higher compared to the numbers observed for *L. braziliensis* and *L. guyanensis* respectively (Figure 1), confirming that the Costa Rica strain is either the result of hybridization or a mixed infection.

Phylogenetic analyses based on the mitochondrial maxicircle points to a member of the *L. guyanensis* species complex as one of the parents

Single Nucleotide Polymorphisms (SNPs) were called jointly across all genomes using bcftools mpileup/call (*16*), retaining only SNPs with a minimum SNP quality (QUAL) of 100, mapping quality of 50 and genotype quality of 60. Genotyping uncovered - across all genomes - a total 1,103,461 SNPs within the 35 major chromosomes and 467 SNPs within the coding region of the mitochondrial maxicircle. A phylogenetic network reconstructed with SplitsTree (*17*) using nuclear SNPs showed that the Costa Rica strain occupied a central position between the *L. guyanensis* and *L. braziliensis* species complexes, highlighting its uncertain ancestry (Figure 2). A phylogeny based on the uniparentally inherited mitochondrial maxicircles (*7,18,19*) showed that the Costa Rica strain clustered with *L. guyanensis* (Figure 3), pointing to a member of the *L. guyanensis* species complex as one of the parental species.

Genomic distribution of heterozygous sites suggests that MHOM/CR/2020/StPierre is a hybrid parasite, rather than the result of a mixed infection

When analyzing the genome-wide SNP distribution in non-overlapping 10kb windows (3,091 windows in total), 2,890 windows (93.5%) were found where at least half the SNPs were heterozygous (Figure 4), and only 108 windows (3.5%) were entirely homozygous. The majority of homozygous 10kb windows (95/108, 88%) covered almost entirely chromosomes 1 and 11, the first 140 kb of chromosome 20 and the last 60kb of chromosome 27 (Figure 5). The observation of a largely heterozygous genome that is interrupted by homozygous stretches strongly suggests that the isolate is a hybrid parasite, rather than the result of a mixed infection.

Distribution of allelic read depths at heterozygous sites shows that the hybrid is a triploid parasite, and reveals major recombination breakpoints

The genetic complexity of *Leishmania* infections is of particular interest because of the existence of aneuploidy, which was genomically inferred by investigating allelic read depth frequencies (ARDF) at heterozygous sites and standardized chromosomal read depths (*20*). The genome-wide ARDF distribution was bimodal for the hybrid parasite, with modes 0.33 and 0.67 (Figure 6) suggesting that the hybrid is triploid (*21*), with the exceptions of chromosomes 1 and 11 (no distribution because of absence of heterozygous sites), 3 and 12 (trimodal distributions). Assuming triploidy, standardized chromosomal read depths showed that chromosome 10 was trisomic, chromosomes 1, 3 and 12 were tetrasomic and chromosome 31 was hexasomic (Table 4). Shifts in the ARDF distribution of species-specific alleles between the two modes along chromosomes (Figure 7) represent recombination events that occurred since the hybridization event (*18*) and further exclude the possibility of a mixed infection.

Neighbor-Joining phylogenetic trees

The low bootstrap estimates in the ML phylogenetic trees based on SNPs detected in the telomeric region of chromosome 20 (Figure in main article) and the maxicircle coding region (Figure 3) prompted us to reconstruct a different type of phylogeny for complementary insights. To this end, we reconstructed Neighbor-Joining phylogenetic trees based on the number of nucleotide differences between *Leishmania* strains using the R package ape (*23*), which are shown in Figures 8 and 9.

Table 1. Sequence variation across 11 positions in the multicopy heat-shock protein 70 gene (*hsp70*)*

POSITION on full CDS	SANGER	WGS	H1 (M2904)	H2 (*L. guyanensis*)
504	R	G, A	NA	NA
731	S	G, C	NA	NA
762	R	G, A	NA	NA
1173	R	G, A	NA	NA
1576	K	T, G	T	G
1600	R	A, G	A	G
1632	Y	C, T	C	T
1666	R	G, A	G	A
1669	K	T, G	T	G
1679	R	A, G	A	G
1734	S	C, G	NA	NA

*A 1,245 bp fragment of the *hsp70* locus was sequenced for species typing, revealing ambiguous bases at 11 positions (column 'SANGER'). Underlying alleles were identified through genotyping of Single Nucleotide Polymorphisms (SNPs) after mapping sequencing reads against a single *hsp70* gene sequence of the M2904 reference genome. This revealed heterozygous SNPs at all 11 ambiguous positions: the two alleles in column 'WGS' represent the reference allele (similar to the M2904 consensus sequence) and alternate allele (different to the M2904 consensus sequence), respectively. Haplotypes (columns 'H1' and 'H2') were decomposed for six neighboring ambiguous positions (1576–1679) by extracting 150bp sequence reads covering all six positions.

Table 2. List of 40 publicly and in-house available sequence data from seven *Leishmania (Viannia)* species that were used for whole genome sequence analyses*

Appendix 2 Figure 1. Number of heterozygous versus homozygous sites for each of the 41 *Leishmania* genomes included in this study. ALT = alternate alleles, i.e., alleles different to the reference genome.
Appendix 2 Figure 2. Phylogenetic network as obtained with SplitsTree (*17*) using 1,103,461 genome-wide SNPs called across 41 *Leishmania* genomes. The star indicates the position of MHOM/CR/2020/StPierre. For each strain, sequences were composed based on concatenated SNPs that were each coded by two base pairs, resulting in sequences of 2,206,922 nt. The distance scale on top shows substitutions/sites.
Appendix 2 Figure 3. Midpoint rooted Maximum Likelihood phylogenetic trees based on 467 SNPs called within the mitochondrial maxicircle coding region. Consensus phylogenetic trees were generated from 1,000 bootstrap trees using IQTREE (*22*) under the TN+F+ASC substitution model (TN = unequal transition/transversion rates and unequal purine/pyrimidine rates, *F* = empirical base frequencies, ASC = ascertainment bias correction), which was the best-fit model revealed by ModelFinder as implemented in IQTREE. Assuming that the maxicircle is haploid and because we observed no signatures of heteroplasmy (all SNPs were homozygous), SNPs were coded by one base pair, resulting in sequences of 467 nt. The distance scale (bottom) shows substitutions/sites. Branch support values are presented near each node following 1000 bootstrap replicates. Note that the *L. braziliensis* lineage 2 is closely related to *L. shawi* and positioned with low bootstrap support (41%) within the *L. guyanensis* species complex. This discrepancy between the nuclear (Figure 2) and maxicircle (Figure 3) phylogenies suggest a complex ancestry for the *L. braziliensis* lineage 2, an observation that warrants more detailed analyses in future research.
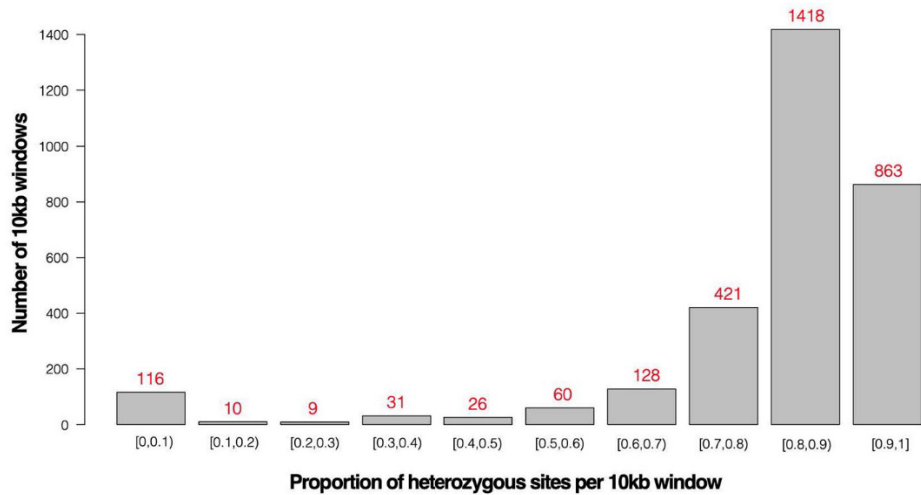

Appendix 2 Figure 4. Number of 10kb windows (y-axis) with a given fraction of heterozygous SNP sites (x-axis).

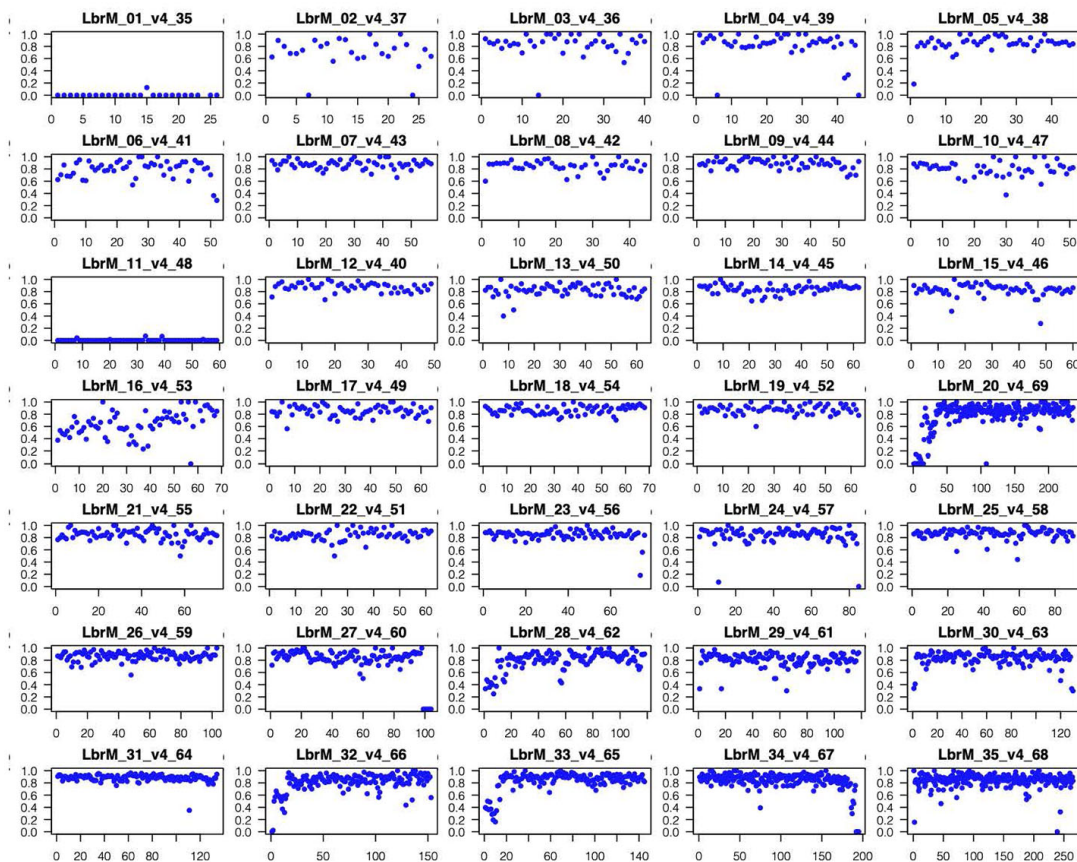

Appendix 2 Figure 5. Fraction of heterozygous sites (y-axis) per 10kb window (x-axis) along each of the 35 chromosomes. The majority of homozygous 10kb windows (95/108, 88%) covered almost entirely chromosomes 1 and 11, the first 140 kb of chromosome 20 and the last 60kb of chromosome 27.
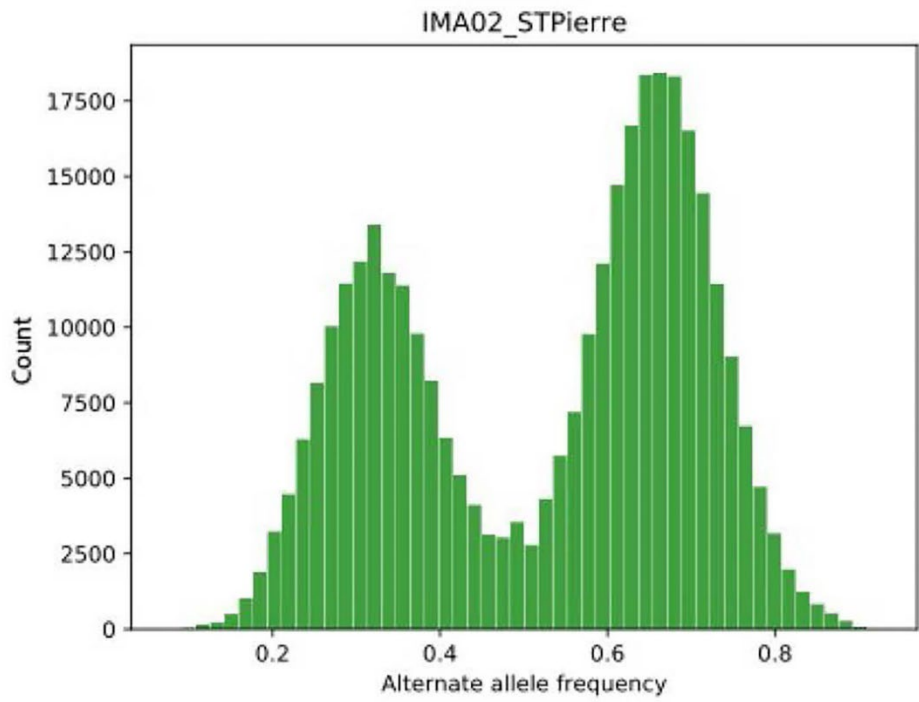

Appendix 2 Figure 6. Genome-wide distribution of read depth frequencies of alternate alleles at heterozygous sites for MHOM/CR/2020/StPierre.
Appendix 2 Figure 7. Distribution of read depth frequencies of all alternate alleles (gray and red dots) at heterozygous sites for each of the 35 chromosomes in the hybrid genome. Red dots reflect alternate alleles that were specific to the *L. guyanensis* species complex, i.e., alleles found in *L. guyanensis* and/or *L. panamensis* and/or *L. shawi* strains and not in any other *Viannia* species. Black bars denote position of major shifts in read depth frequencies, which represent recombination events since the initial hybridization event.
Appendix 2 Figure 8. Neighbor-Joining tree based on the number of nucleotide differences between *Leishmania* strains. Sequences contained 3,015 nt from the telomeric region of chromosome 20 and are the same as used in Figure 1 of the main text. Node support is based on 1,000 bootstrapped phylogenetic trees.
Appendix 2 Figure 9. Neighbor-Joining tree based on the number of nucleotide differences between *Leishmania* strains. Sequences contained 467 nt from the maxicircle coding region and are the same as used in Figure 3 of Appendix 2. Node support is based on 1000 bootstrapped phylogenetic trees.
