Although it is known that coronavirus disease 2019 can present with a range of neurological manifestations and in-hospital complications, sparse data exist on whether these initial neurological symptoms of coronavirus disease 2019 are closely associated with post-acute neurological sequelae of SARS-CoV-2 (severe acute respiratory syndrome coronavirus 2; PANSC) and whether female versus male sex impacts symptom resolution. In this international, multi-centre, prospective, observational study across 407 sites from 15 countries (30 January 2020 to 30 April 2022), we report the prevalence and risk factors of PANSC among hospitalized adults and investigate the differences between males and females on neurological symptom resolution over time. PANSC symptoms included altered consciousness/confusion, fatigue/malaise, anosmia, dysgeusia and muscle ache/joint pain, on which information was collected at index hospitalization and during follow-up assessments. The analysis considered a time to the resolution of individual and all neurological symptoms. The resulting times were modelled by Weibull regression, assuming mixed-case interval censoring, with sex and age included as covariates. The model results were summarized as cumulative probability functions and age-adjusted and sex-adjusted median times to resolution. We included 6862 hospitalized adults with coronavirus disease 2019, who had follow-up assessments. The median age of the participants was 57 years (39.2% females). Males and females had similar baseline characteristics, except that more males (versus females) were admitted to the intensive care unit (30.5 versus 20.3%) and received mechanical ventilation (17.2 versus 11.8%). Approximately 70% of patients had multiple neurological symptoms at the first follow-up (median = 102 days). Fatigue (49.9%) and myalgia/arthritis (45.2%) were the most prevalent symptoms of PANSC at the initial follow-up. The reported prevalence in females was generally higher (versus males) for all symptoms. At 12 months, anosmia and dysgeusia were resolved in most patients, although fatigue, altered consciousness and myalgia remained unresolved in >10% of the cohort. Females had a longer time to the resolution (5.2 versus 3.4 months) of neurological symptoms at follow-up for those with more than one neurological symptom. In the multivariable analysis, males were associated with a shorter time to the resolution of symptoms (hazard ratio = 1.53; 95% confidence interval = 1.39–1.69). Intensive care unit admission was associated with a longer time to the resolution of symptoms (hazard ratio = 0.68; 95% confidence interval = 0.60–0.77). Post-discharge stroke was uncommon (0.3% in females and 0.5% in males). Despite the methodological challenges involved in the collection of survey data, this international multi-centre

prospective cohort study demonstrated that PANSC following index hospitalization was high. Symptom prevalence was higher and took longer to resolve in females than in males. This supported the fact that while males were sicker during acute illness, females were disproportionately affected by PANSC.

Keywords: COVID-19; SARS-CoV-2; neurological complication; neurological long COVID; post-acute neurological sequelae of SARS-CoV-2 (PANSC)

Graphical Abstract

Introduction

Despite multifaceted global efforts in public health measures such as vaccination and medical treatments that have improved the overall outcome of coronavirus disease 2019 (COVID-19), the rapid evolution of severe acute respiratory

syndrome coronavirus 2 (SARS-CoV-2) with multiple variants, coupled with complex social, economic and political ramifications, has hindered a return to pre-pandemic normalcy. Moreover, reports on post-acute sequelae of SARS-CoV-2 infection (PANSC or long COVID) have accumulated after the declaration of the COVID-19 pandemic in

March 2020. COVID-19 can cause long-term symptoms that can persist for months or even years after acute COVID-19 infection.^{1,2} The intensity of these symptoms can vary in severity from mild to debilitating. Among long COVID symptoms, neurological symptoms are of particular public health concern and societal burden, which are increasing in prevalence over time as millions of people are infected with COVID-19.^{3,4}

Although it is well established that acute COVID-19 infection can present with neurological manifestations and in-hospital complications,⁵⁻⁸ sparse data exist regarding whether these initial neurological symptoms and presentations of COVID-19 are closely associated with post-acute neurological sequelae of SARS-CoV-2 (PANSC). Despite many reports on the incidence and risk factors of long COVID over the last few years,⁹⁻¹¹ high-quality evidence focused on 'neurological' long COVID is currently limited. Therefore, a robust large-scale international multi-centre research is necessary to study the prevalence, risk factors and trajectory of long-term PANSC after acute COVID-19 infection, especially for those with COVID-19 hospitalization. Prior studies reported a significant association between female sex and long COVID.^{10,12} However, most studies did not and do not report separate data between sexes on neurological long COVID. Therefore, the primary aim of this study was to describe the prevalence and risk factors of persistent long-term PANSC and post-discharge neurological complications of COVID-19 among hospitalized adults from a large multi-centre COVID-19 registry, the International Severe Acute Respiratory and emerging Infection Consortium (ISARIC) COVID-19 database; a secondary aim was to investigate the impact of female sex on long-term PANSC resolution over time.

Materials and methods

The original study protocol was approved by the World Health Organization Ethics Review Committee, and local ethics approval was obtained for each participating country and site according to local requirements. Patient consent was obtained for a follow-up survey. De-identified data were submitted to the ISARIC database by direct entry to Research Electronic Data Capture (REDCap, version 8.11.11, Vanderbilt University, Nashville, TN, USA), hosted by the University of Oxford or by secure file transfer when locally managed data collection systems were used. All data submitted to the ISARIC data platform were harmonized to the CDISC SDTM standard (Study Data Tabulation Model; version 1.7, Clinical Data Interchange Standards Consortium, Austin, TX, USA). A full description of data collection and curation methods is available.¹³

Study design

Data from a multi-centre, international observational study were analysed to ascertain the prevalence and characteristics of long-term PANSC and neurological complications after a

discharge from acute COVID-19 hospitalization. Patient data were collected according to the ISARIC COVID-19 Follow-Up Study Protocol, a prospective study of COVID-19 patients to assess frequency and risk factors for long-term health and psychosocial consequences of COVID-19.^{14,15} The original ISARIC registry included hospitalized patients with COVID-19 symptoms and laboratory-confirmed SARS-CoV-2. A subset of hospitalized patients with COVID-19 were assessed using received standardized case report forms (CRFs) post-discharge (ISARIC Global Follow-Up Tier 1 Survey: CRFs available in [Appendix I](#)) to do a follow-up and collect long-term physical and psychosocial sequelae. We analysed survey items related to PANSC and post-discharge neurological complications.

Available data are described in the ISARIC Global follow-up protocol and CRFs (<https://isaric.org/research/covid-19-clinical-research-resources/covid-19-long-term-follow-up-study-old/>).^{15,16} The hospitalization data including presentation and in-hospital neurological complications⁸ were linked with the follow-up survey data by a unique participant identifier. Serial follow-up was continued every 3 months post-discharge for up to 12 months. Individuals were recruited for the follow-up study at post-COVID outpatient units. All presenting individuals were invited to join the study. Patients are referred to these units from various sources, including emergency departments, admission wards and family doctors in the recruiting regions. Although all patients admitted with acute COVID-19 during the recruitment period were invited to participate in follow-up, only a random sampling of patients were invited due to resource constraints.

Cohorts

The study cohort for analysis included all patients aged 18 years or over enrolled in the ISARIC COVID-19 Follow-Up Study with confirmed COVID-19 infection who were hospitalized with symptomatic COVID-19 between 30 January 2020 and 30 March 2022. We excluded patients in whom information on hospital admission and discharge dates, sex, intensive care unit (ICU) admission, neurological manifestations/complications and neuropsychiatric follow-up data was missing ([Fig. 1](#)).

Participants were followed up regularly for up to a year post-discharge. Eligible participants completed one or more surveys, with the first survey completed at least 1-month post-discharge from their hospitalization (data completeness available in [Supplementary Table 1](#)). The Tier 1 initial survey was used at the initial follow-up time point (at 3 months post-discharge) and repeated every 3–6 months thereafter. The survey was designed for assessment via patient self-completion, administered via an online link or as a paper form, or by a clinician via in-clinic or telephone assessments during in-person follow-up.

Definitions

Neurological symptoms, as collected at index hospitalization and during follow-up assessments, included altered

Figure 1 A study flow diagram. A flow diagram of the study cohort who participated in a long-term outcome survey.

consciousness/confusion, fatigue/malaise, anosmia, dysgeusia and muscle aches/joint pain. Long-term complications after discharge from COVID-19 admission included stroke/transient ischaemic attack (TIA), deep vein thrombosis (DVT), pulmonary embolism (PE), heart attack and kidney problems.

Outcomes

The primary outcome was the presence of PANSC and post-discharge stroke/TIA at each follow-up time. The secondary outcome was PANSC symptom resolution, accounting for associations with known risk factors with sex (female versus male) as a covariate of interest.

Statistical analysis

Respondent characteristics collected at initial acute COVID-19 hospitalization were summarized for the full analysis cohort and by sex. All continuous variables were summarized as medians and quartiles; categorical variables were summarized as frequencies and percentages. Characteristics covered respondent demographics, comorbidities, neurological symptoms reported at admission, in-hospital neurological complications, ICU admission, mechanical ventilation, extracorporeal membrane oxygenation (ECMO) and hospital length of stay. The reported prevalence of neurological symptoms was estimated at index hospitalization and initial survey follow-up. Overall and sex-specific prevalences were estimated by crude and

age-adjusted rates per 100 hospital discharges with 95% confidence intervals (CIs).

The analysis of long-term neurological outcomes considered the time to the resolution of individual neurological symptoms and the resolution of all neurological symptoms present at initial hospitalization. Two definitions for symptom resolution were considered based on longitudinal survey responses. For the primary analysis, symptom resolution was defined as the first survey date where a participant reported the symptom as absent. As a sensitivity analysis, symptom resolution was defined by participant responses at their last known date of survey follow-up. Resulting times were modelled by Weibull regression, assuming mixed-case interval censoring, with sex and age included as covariates. Model results were summarized as cumulative probability functions and age-adjusted and sex-adjusted median times to resolution. Additional multivariable analyses considered ICU status, year of acute illness, hospital length of stay and reported in-hospital neurological complications. Further details on the methods are provided in [Supplementary File 1](#).

Results

The initial survey cohort included 9824 adult patients hospitalized due to COVID-19 from 407 sites and 15 countries ([Fig. 1](#)). Of these, 6862 participants satisfied the inclusion criteria as a final study cohort. Initial follow-up assessment occurred at 102 days [median, interquartile range (IQR) = 77–183 days] following discharge from the index hospitalization. [Supplementary Tables 1 and 2](#) and

Figs. 1 and 2 further describe data completeness, survey timing, frequency and response rate. For our analysis of time to symptom resolution, available participant numbers were as follows: 2971 (0–3 months), 3188 (3–6 months), 1514 (6–9 months) and 2792 (9+ months). The median time to participation loss to follow-up was 6 months (Supplementary Fig. 8).

Baseline characteristics

Overall, 6862 participants were analysed (39.2% females) with a median age of 57 years (IQR = 46–67 years; Table 1). Most participants were recruited from high-income countries, with European and Asian regions accounting for 98.2% of the study cohort. A geographic breakdown and summary of comorbidities are given in Supplementary Table 3. Males and females had similar baseline characteristics, though neurological symptoms at hospital admission for acute COVID-19 were marginally more common in females than in males (Table 1). Fatigue (54.9%) and myalgia (34.8%) were the most frequently reported neurological symptoms at hospital admission. Fatigue was most frequently reported together with myalgia, dysgeusia and anosmia (Supplementary Fig. 3 and Supplementary Fig. 4). Neurological complications of COVID-19 during hospitalization were uncommon (1.1%); stroke was more common in males than in females (Supplementary Table 4). Of hospitalized patients, 26.5% were admitted to ICU, 15.1% received mechanical ventilation and none received ECMO. More males than females were admitted to the ICU (30.5 versus 20.3%) and received mechanical ventilation (17.2 versus 11.8%; Table 1).

Post-discharge stroke

Approximately 1.1% of male and female participants experience one or more neurological complications during hospitalization (Table 1). During survey follow-up, stroke/TIA was uncommon: 0.3% in females and 0.4% in males. Other complications including DVT, PE, heart attack and kidney problems were infrequent in both males and females (0–2% range).

PANSC

Approximately 70% of patients had more than one neurological symptom upon initial follow-up (median follow-up time = 99 days, IQR = 79–177 days; Supplementary Table 2). Fatigue (49.9%; 95% CI = 47.6–52.4; age-standardized: 47.9; 45.1–50.9 cases per 100 discharges) and myalgia/arthritis (45.2%; 95% CI = 42.4–48.1; age-standardized: 43.8; 40.8–47.0 cases per 100 discharges) were the most frequently reported symptoms of PANSC. Seventy-five per cent of female participants reported one or more persistent neurological symptoms at initial follow-up (95% CI = 71.4–79.5; age-standardized: 73.2; 67.5–79.5 cases per 100 discharges). Reported prevalence in females was generally higher than in males for all PANSC symptoms at initial follow-up

(Table 2). Dizziness, visual problems and sleeping problems were reported more frequently by females than males (Supplementary Fig. 5).

At 12 months, dysosmia and dysgeusia were resolved in almost all patients though fatigue, altered consciousness and myalgia remained unresolved in more than 10% of the cohort. Males had greater recovery of symptoms at 12 months compared with females (Supplementary Table 5). The median time to the resolution of one or more neurological symptoms reported at acute hospitalization was generally longer in females than in males. Median times to symptom resolution generally increased with age, being the longest times reported by participants aged between 45 and 65 years (Fig. 2; Supplementary Fig. 6). Patients with more than one neurological symptom at hospitalization for acute COVID-19 had a prolonged time to resolution [5.2 months in females and 3.4 months in males; hazard ratio (HR) = 1.45; 95% CI = 1.31–1.60; Supplementary Table 5]. Patients who experienced neurological complications during hospital admission had a similar median time to recover compared with those who did not (Supplementary Fig. 7).

The cumulative probability of the resolution of altered consciousness was similar between females and males (Fig. 2; Supplementary Fig. 8). For all other symptoms, males had a far greater chance of symptom resolution at any given time.

Multivariable analysis of PANSC

Male sex was significantly associated with a shorter time to the resolution of neurological symptoms (HR = 1.53; 95% CI = 1.39–1.69; Fig. 3; Supplementary Table 6). ICU admission and COVID-19 infection in 2021 (versus 2020), but not prolonged hospital length of stay, were significantly associated with a longer time to symptom resolution (Fig. 3). Multivariable results were similar between the full analysis cohort and the subset of participants evaluated for in-hospital neurological complications. The presence of in-hospital neurological complications was not associated with resolution time (HR = 1.16; 95% CI = 0.48–2.45; Supplementary Tables 6 and 7).

Discussion

In this study, we present results from a large international multi-centre observational cohort of patients (ISARIC) who reported PANSC symptoms at regular time points over a 1-year period following an index hospitalization with acute COVID-19 disease. Our study is unique in reporting focused ‘neurological’ long COVID symptoms for up to 1 year and the analyses on time to symptom resolution. We showed that a large proportion of patients (70%) had more than one neurological symptom upon initial follow-up at ~3 months, with females having higher frequencies and a longer time to the resolution (5.2 versus 3.4 months) of PANSC symptoms. The cumulative probability of the resolution of PANSC was far greater in males at any given time.

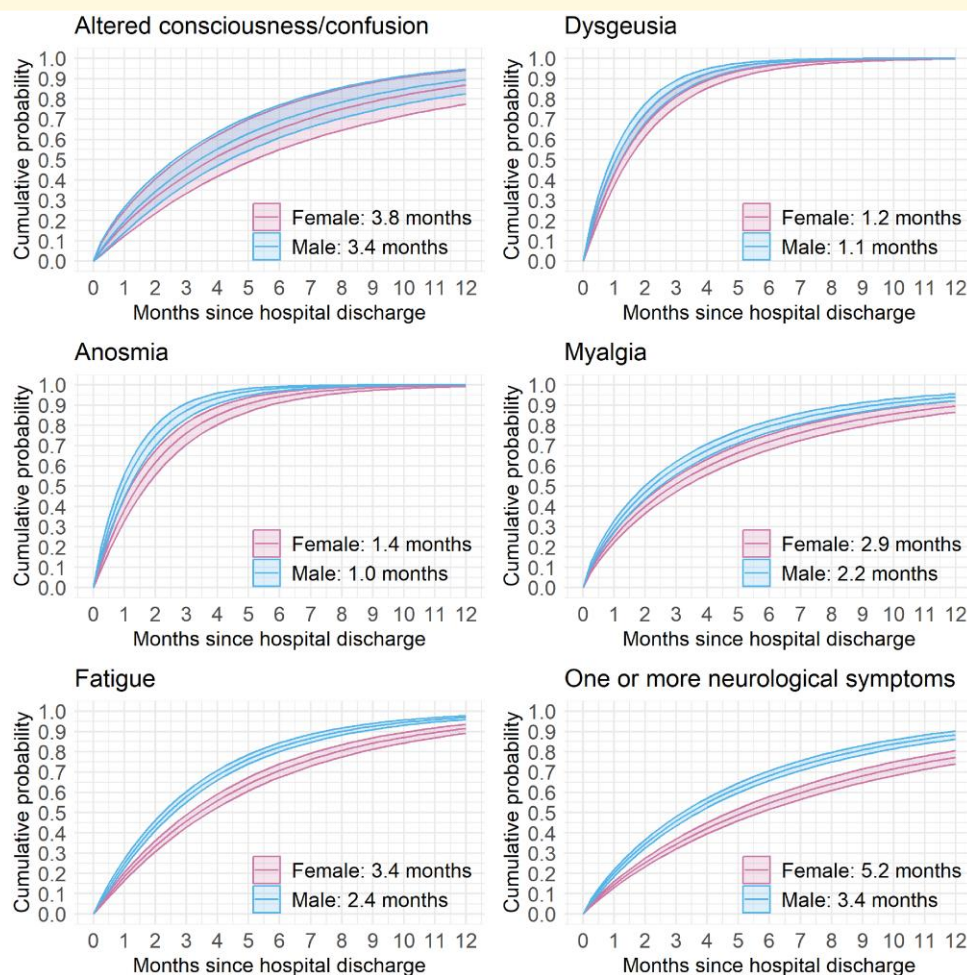

Figure 2 Symptom resolution probability. Cumulative probability functions [estimate (95% CI)] to neurological symptom resolution stratified by sex (female = pink, male = blue; adjusted for age = 60 years). Median times for symptom resolution for the corresponding sex are annotated (also see [Supplementary Table 5](#)). Sensitivity analysis results are provided in [Supplementary Fig. 8](#).

This is in keeping with prior work where the female sex has been reported as a significant risk factor for long COVID (not specific to PANSC), with a meta-analysis of 7 studies and 386 234 patients demonstrating an odds ratio of 1.48 (95% CI = 1.17–1.86).^{12,17} Similarly, over half (1100 of 2103, 52%) of responders in a Latin American study reported that long COVID symptoms were more commonly reported by females (64.0%).¹⁸ The findings may be associated with females generally having more depression and anxiety; however, our study did not have those specific variables. The age group most affected with long COVID varied from young adults (21–40 years)¹⁸ to older adults (≥ 50 years)¹⁹ in different studies. It is noteworthy, unlike our study, that the aforementioned studies have not investigated specific PANSC, which may have resulted in some inconsistent findings on age. Our study demonstrated middle-aged participants (40–65 years) were more affected by PANSC in our study ([Fig. 3](#)).

Severe acute respiratory distress syndrome (ARDS) is a known risk factor for long-term cognitive and psychiatric

impairment.^{20,21} Interestingly, we noted there were substantially more males than females who were admitted to ICU (31 versus 20%) and received mechanical ventilation (17 versus 12%; [Table 1](#)). This did not translate into more PANSC on follow-up, further highlighting the sex discrepancy in PANSC. Also, our study highlights that, in addition to a greater prevalence, symptom resolution takes longer in females than in males, which provides a new unique perspective to the current knowledge of long COVID, which was not reported in COVID-19 or general ARDS literature.

The aetiology of long COVID and of neurological symptoms of long COVID are areas of active research and are suspected to be multi-factorial.²² Several hypotheses implicate both the nervous system and the systemic pathogenic mechanisms such as SARS-CoV-2 viral persistence and neuroinvasion, abnormal immunological response (subacute to chronic), autoimmunity, coagulopathies and endotheliopathy with microvascular clot formation, which can contribute to hypoxic neuronal injury and blood–brain barrier dysfunction.²²

Table 1 Baseline demographic and index hospitalization characteristics

Characteristic	Full cohort (n = 6862)	Female (n = 2691)	Male (n = 4171)

Lastly, we identified that most survey participants were enrolled from high-income countries represented in the global ISARIC cohort. This geographical distribution differed from the total number of patients included in the WHO-ISARIC Clinical Characterization Protocol evaluated for neurological symptoms and in-hospital complications. Fewer survey participants from low-income and middle-income countries highlight the need to strengthen research capacity and develop strategies and tools to support effective patient follow-up in low-resource healthcare systems.¹³

Limitations

This study has several limitations that should be considered when interpreting the main findings. A key among these is the methodological challenges of assessing patient symptoms and complications using remote clinician lead and self-assessments during pandemic constraints and common issues encountered when conducting multi-site longitudinal studies. First, as

participant recruitment and follow-up were contingent on resourcing at individual study sites, data were collected at irregular intervals and subject to loss to follow-up. Second, it is likely that the study cohort was subject to a degree of selection bias, related to challenges in recruiting and retaining participants following acute COVID-19 hospitalization. We further considered population differences by reporting sex-specific prevalence as crude and age-standardized rates. Third, our study did not provide any mechanistic insights into long-term PANSC. Fourth, the rapid evolution of COVID-19 disease and its treatment with antiviral therapy such as nirmatrelvir or steroids were not well captured in the database, which limited our ability to investigate treatment impact on PANSC other than possible associations. Finally, multivariable analyses were limited in terms of adjustment for patient-level characteristics related to disease severity, for example, the use of mechanical ventilation. Limiting these analyses was intended to reduce the risk of reporting distorted associations from collider bias,²³ common in observational studies.

Table 2 The observed prevalence of neurological symptoms at initial survey follow-up, stratified by the presence or absence at acute COVID-19 hospitalization

	Full cohort				Female		Male	
	Present		Absent		Present	Absent	Present	Absent
	n (%)	95% CI	n (%)	95% CI	n (%)	95% CI	n (%)	95% CI

CI, confidence interval; COVID-19, coronavirus disease 2019. Prevalence estimates are reported as total reports/total respondents (%), crude rates per 100 hospital discharges [estimate (95% CI)] and age-standardized rates per 100 hospital discharges [estimate (95% CI)].

Figure 3 Risk factors for time to symptom resolution. (A) The median time (months, y-axis) to symptom resolution is based on the patient's age (x-axis). **(B)** Multivariable analysis for time to symptom resolution for those with one or more neurological long COVID symptoms.

Other study limitations relate to the scope of analyses possible on standardized data collections. First, the spectrum of neurological psychiatric manifestations and complications of COVID-19 is broader than the CRF terms included in the patient registry and survey. Secondly, due to the data collection methods used, mortality was recorded only if data collectors were notified of deaths before or while attempting to follow up with a participant. In cases where participants could not be contacted, the reason for loss to follow-up could not be determined from available data. Thirdly, it was not possible to assess the implications of PANSC on quality of life, as formal quality-of-life questionnaires and neurocognitive or psychiatric assessments suffered from significant missingness. Challenges exist in defining and capturing PANSC and establishing causation, especially in ICU patients with ARDS, where there is evidence of the long-term burden suffered by survivors. A more intense follow-up with defined endpoints would have allowed a more detailed analysis, but our study was a pragmatically driven extension of the initial WHO-ISARIC Clinical Characterization protocol (<https://isaric.org/research/covid-19-clinical-research-resources/clinical-characterisation-protocol-ccp/>).²⁴ Most follow-up participants were from high-income countries, whereas the

majority of patients in the ISARIC COVID registry were from low-income/middle-income countries. Finally, patient recruitment strategies varied between sites and were subject to staff and resource limitations, introducing the possibility of recruitment bias. As the heterogeneity of PANSC reported in the literature as it relates to long COVID is a challenge, our study with a large sample size (407 sites; 15 countries) offers an advantage. In a scoping review conducted in January 2021, out of 120 papers, there was 1 randomized clinical trial, 22 were cohort and 28 were cross-sectional studies, none of which focused on PANSC symptoms, thus highlighting the importance of our study.²⁵

Conclusion

This international multi-centre prospective cohort study demonstrates that PANSC after hospitalization is high, with a higher prevalence in females and a longer time to resolution. This supports the fact that females are disproportionately affected by PANSC, although males were admitted to ICU more often and were treated with mechanical ventilation more often than females. Stroke is an uncommon neurological

complication after COVID-19 discharge. Given the burden of disease, further work is needed regarding the screening and treatment of long-term neurological symptoms after COVID, particularly in low-resource healthcare settings.

Acknowledgements

The investigators acknowledge the support of the members of the ISARIC follow-up working group including: John Amuasi, Margarita Andreeva, Sergey Avdeev, Anna Beltrame, Polina Bobkova, Danilo Buonsenso, Denis Butnaru, Muge Cevik, Yash Doshi, Thomas Drake, Anne Margarita Dyrhol-Riise, Michael Edelstein, Natalie Elkheir, Victor Fomin, Aysylu Gamirova, Petr Glybochko, Claire Hastie, Haider Hirkani, Antonia Ho, Jan Cato Holter, Waasila Jassat, Edwin Jesudason, Valentina Kapustina, Pulak Kedia, Krish Kherajani, Anders Benjamin Kildal, Sulaiman Lakoh, Sakshi Lath, David Lowe, Laura Merson, Caroline Mudara, Daniel Munblit, Srinivas Murthy, Nikita Nekliudov, Carlo Palmieri, Prasan Kumar Panda, Drashti Patel, Ellen Pauley, Jill Pell, Simone Piva, Matteo Puntoni, Jordi Rello, Luis Felipe Reyes, Ankana Satya, Janet T Scott, Rohan Shetty, Anastasia Shikhaleva, Louise Sigfrid, Girish Sindhvani, Ekaterina Spiridonova, Andrey Svistunov, Lance C.W. Turtle and Gayatri Vishwanathan. The investigators acknowledge the support of the COVID clinical management team, AIIMS, Rishikesh, India; the dedication and hard work of the Groote Schuur Hospital Covid ICU Team and supported by the Groote Schuur nursing and University of Cape Town registrar bodies coordinated by the Division of Critical Care at the University of Cape Town; the Liverpool School of Tropical Medicine and the University of Oxford; Imperial NIHR Biomedical Research Centre; the dedication and hard work of the Norwegian SARS-CoV-2 study team; and preparedness work conducted by the Short Period Incidence Study of Severe Acute Respiratory Infection. This work uses data provided by patients and collected by the NHS as part of their care and support #DataSavesLives. The data used for this research were obtained from ISARIC4C. We are extremely grateful to the 2648 frontline NHS clinical and research staff and volunteer medical students who collected these data in challenging circumstances and to the patients and their families for their generosity of making individual contributions in these difficult times. The COVID-19 Clinical Information Network (CO-CIN) data were collated by ISARIC4C Investigators. We also acknowledge the support of Jeremy J. Farrar and Nahoko Shindo.

Data availability

The data that underpin this analysis are highly detailed clinical data on individuals hospitalized with COVID-19. Due to the sensitive nature of these data and the associated privacy concerns, they are available via a governed data access mechanism following the review of a data access committee. Data can be requested via the IDDO COVID-19 Data Sharing Platform (<http://www.iddo.org/covid-19>). The Data Access Application, Terms of Access and details of the Data Access Committee are available on the website. Briefly, the requirements for access are a request from a qualified researcher working with a legal entity who has a health and/or research remit, and a scientifically valid reason for data access that adheres to appropriate ethical principles. The full terms can be accessed at <https://www.iddo.org/document/covid-19-data-access-guidelines>. A small subset of sites that contributed data to this analysis have not agreed to pooled data sharing as above. In the case of requiring access to these data, please contact the corresponding author in the first instance who will look to facilitate access.
