Keywords: Model-based coding, Rendering, Level Sets.

Abstract

We address the problem of representing captured images in the continuous mathematical space more usually associated with certain forms of drawn ('vector') images. Such an image is resolution-independent so can be used as a master for varying resolution-specific formats. We briefly describe the main features of a vectorising codec for photographic images, whose significance is that drawing programs can access images and image components as first-class vector objects. This paper focuses on the problem of rendering from the isochromic contour form of a vectorised image and demonstrates a new fill algorithm which could also be used in drawing generally. The fill method is described in terms of level set diffusion equations for clarity. Finally we show that image warping is both simplified and enhanced in this form and that we can demonstrate real histogram equalisation with genuinely rectangular histograms.

1 Introduction

A common problem in distributing digital images and movies is that of catering for varying image or film formats. For example a short sequence of a feature film may be shown on standard TV (768x576), HDTV (1920x1024), internet video (various), or even mobile phones (anything from 384 x 256 upwards). If shown for publicity reasons the producers will want this to be shown at the best quality possible. In effects houses which concentrate on advertising a significant proportion of time is spent just converting between the various digital formats on which the advertisement is to be shown. The problem arises because all digital images have to be sampled in order to be seen at all, but different kinds of display device have, of necessity, to show the images at differing resolutions. Vector formats, historically associated with drawn images rather than with photographs, can provide such a resolution-independent rule but none of the existing fully automatic fill rules for vector formats work well on photographic images. This paper describes a new fill regime based on diffusion which results in images which are visually indistinguishable from their originals after conversion into and out of a vector representation.

Figure 1: (i) Original digital photo

(ii)Rendered: flat-fill

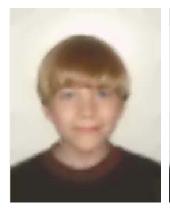

(iii) Rendered: interpolated fill

There are a number of systems and plug-ins available to turn images into vector form (e.g. Adobe Live TraceTM) but they are all compromised by the absence of a good rule for determining varying colour values in a continuous field. Tools like Live TraceTM extract isochromic contours from sampled images but have to extract a sufficiently large number of contours to preserve the illusion of a smooth surface on a sampled display. This is because the usual rule for automatically filling between contours is to provide a constant colour (here called flat fill) in the viewable rasterised version of the image so the results can be thought of as providing a series of step changes in colour values rather than a continuous variation in those values. In Figure 1 ii we have used a flat fill regime on an image which was vectorised for a diffusion-based fill regime of the kind described later in this paper. The diffusion-based approach allows for the use of fewer contours without compromise to the appearance of smoother parts of the image and this has shown up a particular weakness of flat fill in the form of visible bands of colour changes (Mach bands). Indeed the usual application of such systems is to produce an artistic effect rather than a realistic outcome.

In this paper we show how to resolve this problem. As the contours can be thought of as a model of the image they need to be converted to a sampled image format in order to be seen on raster display devices. Thus a rendering process, entirely analogous to rendering processes used in 3D graphics, is required. The problem here is, if flat-fill is insufficient, how do we determine the intermediate pixel values between contours when rendering back to the sampled form? This problem and this paper's contribution to its solution are best illustrated in Figures 1 i-iii above. In Figure 1-ii the straightforward approach of flat fill has been taken. More explicitly each contour footprint, here defined as the image region uniquely enclosed by a contour, has been filled with a constant 'average' colour. In Figure 1-iii a diffusion-based interpolation technique (described in section 4) has been used instead. Each rendered image was rendered from the same contour set. In Figure 1 ii the different outcomes are quite noticeable; flat fill shows Mach-banding artefacts which are wholly absent with the interpolated fill of Figure 1-iii. As can be seen in Figure 1-iii the interpolating fill technique produces satisfactory results even though a quite simple rule has been used to determine which contour levels to use in the vector form.

A major problem in determining this vector form is that of determining how many contours to use. A naïve approach would be to use one contour for every unit of colour quantisation but this not only produces far more contours than are needed for a visually faithful reproduction of the image but also far more detail in defining each contour than is needed. If flat fill is used within contour boundaries the inefficient naïve approach is the only technique which will assure an artefact-free result. Techniques based on morphological principles (e.g. [17]) do this and, while we reference these techniques as part of the historical record, we would like to draw a distinction between the morphological approach and ours, notably in terms of the number of levels required for a visually satisfactory rendering. In such an approach all that would be needed for a visually faithful rendering would be to fill the contour with an 'average' colour quantised to be the border colour. In fact far fewer contours are needed in practice as we show here. To illustrate the contours without too much visual confusion we chose the outof-focus image Figure 2(i). Here the images have been rendered from contour sets representing the YUV components of a colour image. As can be seen in Figure 2 iii-iv and Figure 3 ii-iii there is very little detail in the U, V components so the size of the dataset is dominated by the Y-component. (This remains true even with a sharp, high-definition image.) The Y component (grey-scale) is held in levels-of-10 256-bit quantisations, i.e. the colours 127, 127+10 etc. 127-10 etc. of which there are 25 altogether; while the U,V components are held in levels-of-5 (so 127, 127-5, 127-10 etc.) of which there are 49 altogether.

(iii) U-component in grey-scale (iv) V-component in grey-scale

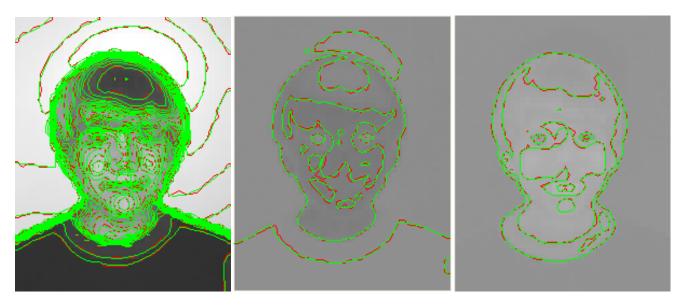

Figure 3 (i) Y-component 2-ii contourised (ii) U-component 2-iii contourised (iii) V-component 2-iv contourised

This selection of contour levels has proved satisfactory for the images we have used here (although it is possible to find counter-examples). The contours for the YUV components of Figure 2-i are shown in Figure 3. The red contours are unsmoothed versions of the green ones. Smoothing is achieved by 'snapping' together end-point tangents if they fall within a certain threshold of being directionally opposite.

This paper is structured as follows. The next section (2) covers previous work in this area, some of which reaches back to the earliest days of computer graphics. Section 3 discusses the main features of the vectorising codec we have used here, which has an encoder which works from a raster image to produce a vector image format and a decoder which renders the vector format back into a raster image. Section 4 discusses the decoding stage in more detail, and in particular the principles behind the diffusionbased interpolating fill process. We will see that this fill could be used just like any other area fill technique used in rendering vector format images, and on its own would give a drawing program (or Scalable Vector Graphics - SVG[5] - interpreter) the ability to reconstruct contourised images to whatever degree of fidelity is required. Section 5 shows the results from some test images. Section 6 discusses some common image manipulation functions, including histogram equalisation, and here shows the consequences of producing truly rectangular histograms which are unachievable using sample-based techniques. Section 7 will conclude the paper and review where this work places vector image formats.

2 Previous work

Vectorising (contourising) as applied to an array of sample points is a technique whose origins go back to geographical information systems [23], where contour maps were to be produced from spot height surveys, and was first applied directly to photographic images by Matheron [9] and later by Serra[17] (these are the early references to the morphological approach). At about the same time Nakajima et al. [10] (a more accessible reference is Agui et al. [1]) proposed an approach more closely allied to the techniques of computer graphics. The fill methods used in image reconstruction in all these references is flat fill. More recently Price & Barrett [14] and Sun et al. [20] have proposed methods for generalising from flat fill while keeping the same number of contours [20] or sample points [14] by building an adaptively subdivided mesh where colours are associated with mesh intersection points, although some interaction is required to determine the starting shape of the mesh. Both the method of contour finding and mesh generation (Live TraceTM[14][20] and gradient mesh tool[20] respectively) are available in commercial drawing packages but the papers focus on smooth colour interpolation and mesh optimisation for minimal dataset size. However this approach simply swaps one set of sample points for another more feature-oriented set, as befits the type of calculation they want to do, and offers no help to calculations like histogram equalisation or processes involving preserving features of the isosurface topology (The isosurface is defined by a given set of isochromic contours selected from the set of quantised colours used).

Another approach is to use a data-dependent triangulation (DDT) based on a range of techniques such as the approach used by Yu et al. [24]. Here the idea is to adaptively triangulate the image so that each vertex is associated with a colour and the image is reconstructed by a barycentric interpolation between the colour values associated with each vertex. The main part of the

algorithm involves an initial convex hull triangulation based on image sample points so that triangle edges approximately align themselves with isochromic contours while optimising an overall smoothness function, and then improves this triangulation by edge reconnections and deletions. While the contours are not found explicitly, the alignment of some edges will correspond to image features and the optimisation steps are aimed at enhancing these correspondences. This in effect replaces a sampled form of the isochromic surface with an approximate triangulation of the continuous isosurface as is commonly done in topology [2]. However, once again there is no support for the kinds of image operation we consider here as for example there is no guarantee that a given isochromic contour will be matched everywhere by a connected set of triangle edges. There is also the question as to whether a planar triangulation will survive an arbitrary (2D) image warping operation.

There are, however, other approaches to the problem of vectorising images than by using isochromic contours, for example the ARDECO approach [7] where a segmentation, filled by the various fills available to SVG. is fitted to an image to within a given error bound, here a threshold. The resulting structure can be made to support statistical image manipulation operations like histogram equalisation in a similar way to our diffusion approach. In fact it is possible to extend 'flat fill' for a uniformly quantised colour space to a diffusion-like fill using the technique of Kim et al. [6] and that would include the simple contourisation model we have used for the images in this paper, but not its generalisations. As the Kim et al.[2006] algorithm attempts to model the isosurface as a smooth continuous surface everywhere other than at edges (so is non-linear anywhere) this complicates the working of an algorithm like histogram equalization, but does provide some degree of support. Another approach which does not use contours, but rather chooses edges as the key feature, is that due to Orzan et al. [11] [12]. Here the idea is to use edge-lines as the vectors and to decorate the lines with colour data. This is then propagated away from the edge using a Poisson equation. When used for images the edge lines correspond to discontinuities in otherwise smooth shading and reconstructed images look a lot like their original forms although the unconstrained use of Poisson equation diffusion results in quite inaccurate diffusion boundaries. It is the insight of Lindeberg [8] (and others) that this inaccuracy tends not to be noticed which Orzan et al. are exploiting here. They also note ([12]) that a similar decorated-edge representation can be used to produce smooth-shaded images of a kind difficult to generate by other means. Similarly the diffusion method described in this paper could be used to generate different forms of smooth-shaded synthetic vector image although the method of control would be quite different.

In the end any accurate method of vectorising a photographic image needs to have some kind of

interpretation of just what a pixel is and in essence we make a different interpretation of an image pixel on input to the interpretation made on output. Two papers which discuss this problem in ways we pay particular attention to are those due to Blinn[3] and to Smith[19]. Blinn[3] discusses eleven distinct ways in which to consider what a pixel actually is and this includes a discussion of the relationship between a sample and a sensor which generate samples, while Smith[19] makes a strong argument for not considering a pixel as being a square over which some simple form of integration is done (e.g. a tent filter). Pixel generation (in the decoder) uses supersamples under the footprint of a convolution kernel, which is quite different to the assumptions about input although the nature of the input environment may be taken into consideration when deciding what the pixel value might be, for example to use noise statistics to determine how closely to approximate the round off in quantisation. In fact we have combined regular 4 x 4 supersamples (sometimes 9 x 9 supersamples on a 4 x 4 sampling grid) by integrating over a square in all our images in this paper without being caught out, but more stringent sampling or averaging regimes are not excluded by our approach.

3 Main features of a vectorising codec

An image vectorising codec starts from a sampled image, typically one obtained from a digital camera, encodes it into an annotated contour set (the level sets) and subsequently decodes it back into a sampled image after image transformation processes are applied to it. In our codec individual contours are represented by closed Bézier chains; contours clipped by the image border are completed by the shape of the border segment which falls within the contour footprint. The contours are found by first finding where they intersect lines between sample points derived from the original pixels. A key aspect of the input process is the explicit assumption that the pixel is contaminated by noise which can arise from any source, quantisation, sensor noise, even numerical inaccuracy, so is essentially of unknown origin. For example when considering the degree of accuracy to which the isosurface is modelled the strictest requirement we can safely make is that the isosurface model lies everywhere inside the error bounds of the pixels.

Pixel error can be modelled in a number of ways, essentially either globally or locally. The accuracy of the value derived from the model is not critical although too crude a model could result in retaining image noise in the final result or a result which loses detail. While more accurate local approaches are covered in Patterson & Willis [13] we should say that all the images in this paper were generated assuming a simple global noise value (±constant around each pixel value) without apparent loss of detail due to that assumption. If we are to attempt to preserve noise statistics in the final image, as suggested earlier, more accurate, local, methods will be needed.

Error terms ε , however derived, can be converted into spatial error δx , δy in the x or y direction by applying the formulae:

$$\delta x = \varepsilon \cdot \frac{\partial \phi}{\partial x}^{-1}$$
, $\delta y = \varepsilon \cdot \frac{\partial \phi}{\partial y}^{-1}$

Here $\phi = \phi(x, y)$ is the continuous approximation of the 'true' isosurface. Accordingly any isochromic contour is derived in terms of an error bound around it, initially identified in the x, y directions and subsequently interpolated as a ribbon of error within which the contour may take any shape which fits. In fact we associate these errors with points on the contour line when fitting the Bézier chain but any fitting algorithm (e.g. the method outlined by Schneider[16] or by Vansichem et al. [21]) has to take into account different values for that error around each sample point. One way to relax this condition is to multiply the derived error values with a constant and the consequence will be to reduce the number of segments in the chain and increase its smoothness. It turns out that failing to take into account the presence of noise results in large numbers of Bézier segments in every contour as it twists and turns around single pixel-sized 'features' which are no more than noise-induced deviations from local correlation. If instead we account for noise adequately we get much smoother curves (with many fewer segments) whose smoothness has, up to a point, no perceptible effect on the resultant render.

Prior to contourisation the original image is re-sized by a factor of two by interpolating additional sample points in x and y respectively. These sample points are interpolated using the modified linear interpolation process described by Carrato et al [4] which biases the result towards one or other of the interpolated pixels in the presence of a large gradient between the sample values. Contours are found first in terms of solving for points on the 'true' contour with associated spatial errors (which are actually a measure of local resolvability) in terms of the contour's intersections with lines through the pixel centres in the x or v direction appropriately. Here we have done this calculation by linear interpolation alone, that is by solving in the appropriate direction for the point where the linear interpolant along x or y is equal to the sought contour value, and then interpolating between the sample errors by the same amount. If a local error had been calculated then it could have been used to determine which degree of interpolation was appropriate on a solution-by solution basis by finding which derivative approximated to zero within the calculated error bounds for derivative[Patt&06]. However past experiments with a pixel-level noise estimator have showed that for the majority of cases (approximately two-thirds in typical images) only linear interpolation could be justified and the rather basic assumptions about noise made here would not justify higher order interpolation anywhere. The resulting polyline approximation to the 'true' contour is simplified by finding the Bézier chain with the fewest segments which fit within the error ribbon the polyline approximation defines.

In an encoder the contour values can be determined by a blind strategy or an adaptive strategy. In this paper we have used a simple but (reasonably) effective blind strategy of pre-selecting the values to be found. As a consequence all the images in this paper are represented by the same choice of contour levels and all the contours are found at the same time by a single scan of the image from top to bottom. Here we examine each pixel to see which contours pass through a bounding box around its centre and then join up the contours by matching adjacent bounding box edges. This approach is only really possible with a blind strategy as an adaptive strategy will of necessity contain a stopping condition based on testing the need for the contour loop under consideration.

The outcome of the process is a hierarchy of contours (including contours R and S) defined in terms of the relation R encloses S and the vector format consists of rules for drawing and filling these contours in order. The decoder 'simply' applies the fill rule for the footprint of each pair of contours in the hierarchy as defined by the footprint of the enclosing contour subtracted from the footprint of all the contours it encloses directly (i.e. with no intervening contours in the hierarchy).

4 Rendering between nested contours

The principal issue in rendering is to use a process which mimics to some degree the fall-off in values of pixels from a higher level to an adjacent lower one. The intention is to develop a simple diffusion-based fill algorithm between levels, as defined by level lines (isochromic contours). We will first develop the idea in familiar level set terms and then show how to implement it without having to solve the differential equations which the invocation of level sets implies. The reason for doing this is that Level Set theory makes the issues clear in a direct and easily visualisable manner but the complexities of solving the equations led us to use known fast, scanline –based methods to give us quick renders.

We derive the formulae in terms of a simple case (Figure 4) of a single outer contour with level value R surrounding a single inner contour level S, and then generalise. We want to arrange for the inner contour $S = \psi(0)$ to first expand (in the terminology of Vincent [22] 'to dilate') at a uniform (unit) speed until it wholly contains R (Figure 4-i). At all times the level line for $\phi(t)$, over the interval $0 \le t \le 1$, gives the shape of the intermediate dilation at instant t which we note is wholly dependent on S and has no connection with the shape of R. If, at the same time,

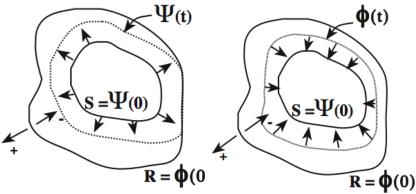

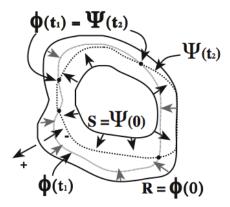

Figure 4(i) dilation of Ψ to include Φ (ii) contraction of Φ to inside Ψ

(iii) matching Φ and Ψ indices

the corresponding level line for R is contracted ('eroded' [22], as in Figure 4-ii) at uniform speed until it falls wholly within S then the level lines for intermediate erosion at time point t_2 , say, will intersect the level lines for dilation in a range around another time point t_1 . These time points t_1 and t_2 now correspond to the times taken to reach the nearest points on **R** and **S** respectively, so define linear distances which can be used to interpolate colours associated with R and S respectively at the points of intersection of these two curves. What we are saying is that for any point inside the region R - S (R with S removed from within it) the shortest distances to the boundaries of R and S respectively determine the interpolation of the colours associated with the bounding levels **R**, **S** at that point. These interior colours will usually vary linearly from the values associated with one contour to the other, but this only happens if the geodesics running through the points in question are straight lines, i.e. the boundaries are not occluded from the point. In more complicated situations the interior colours will vary as though affected by surface tension, which is likely to fit what is actually found.

Taking the outwards direction as positive (as shown in Fig 4-i), the level set equation for the expansion (dilation) of ψ is:

$$\frac{\partial \psi}{\partial t} = K \cdot \frac{\nabla \psi}{|\nabla \psi|} \quad \text{where } K = \begin{cases} 1 \text{ if } \left| dist_{R-S} (\psi(t), R) \right| > 0 \\ 0 \text{ otherwise} \end{cases}$$
 (1)

Here $\psi(t)$ is the expansion of $\psi(0)$ clipped by $R = \phi(0)$. The function *dist* () gives geodesic distances of points in R, R(i) say, from S using the value of t at the points at which $\psi(t) = R(i)$.

We can obtain the morphological distance fields for -R and +S by evaluating equation (1) and its matching partner for the erosion [22] of R, equation (2) as in Figure 4-ii:

$$\frac{\hat{o}\phi}{\partial t} = -K \cdot \frac{\nabla \phi}{|\nabla \phi|} \quad \text{where } K = \begin{cases} 1 \text{ if } \left| dist_{R-S}(\phi(t), S) \right| > 0 \\ 0 \text{ otherwise} \end{cases}$$
 (2)

This will give two Euclidean distances t_1, t_2 , where $\phi(t_1) = \psi(t_2)$ at zero or more points inside R - S (as in Figure 4-iii) so we can calculate the colour values C of those points from the colours C_R, C_S associated with level lines R and S respectively as:

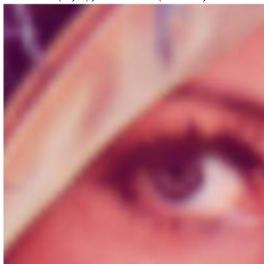

$$\mathbf{C} = \mathbf{C_R} \cdot \frac{t_2}{t_1 + t_2} + \mathbf{C_S} \cdot \frac{t_1}{t_1 + t_2}$$

We have used diffusion twice to give us morphological distances from each point in space in terms of the time to reach each of the two levels (here the speed of travel is unity so time = distance). When normalised by the sum of the distances this gives us an interpolation ratio between the two contour values which is linear for simple geometries but quadratic with a positive curvature - quite similar to the effects of surface tension - when the contour geometry becomes complicated. We refer to this process as double diffusion and note that isochromic lines are in effect interpolants between the shapes of the inner and outer contours, so it should properly be called double diffusion interpolation. For this paper we used a computationally simpler measure than Euclidean distance, namely Manhattan distance, calculated outwards (inwards) from a border defined in terms of those pixels which contained the border contour. The Manhattan distance can be calculated like a fill process in which successive erosions or dilations define an ascending index starting at 1. Although the Manhattan distance is always an overestimate this tends to get normalised by the division of indices calculated in the same way. If the calculation of dilation (or erosion) is carried out in a quantised manner this naturally supports Manhattan distances, but if it is carried out continuously (e.g. by equations 1 and 2) this naturally supports Euclidean distances and the precise calculation of interpolants which are smooth everywhere.

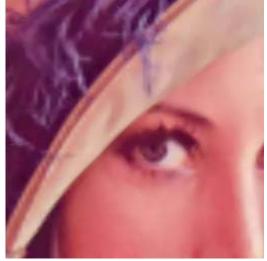

(iii): (i) Scaled x 4 (bilinear)

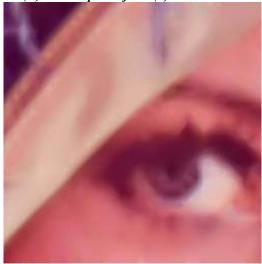

(v): (i) Scaled x 8 (bilinear)

(ii) Rendered from contours (x 1 scale)

(iv) Control points from (ii) scaled x 4

(vi) Control points from (ii) scaled x 8

5. Example applications

Apart from Figure 1 all the examples showing our interpolation approach are applied to the reconstruction of YUV images with Y at intervals of 10 and UV at intervals of 5. In Figure 5-i and we show an original pixel image (the standard test image 'Lena') and its re-rendered equivalent in Figure 5-ii. At intervals of 10 between Y levels the re-render is visually indistinguishable from the original (input spatial resolution 256x257).

Additionally we have shown in Figure 5-iii and 5-v two portions of 'Lena' scaled up by x 4 and x 8 respectively using bilinear interpolation (which is often preferred over higher order methods). As one expects the detail becomes more blurred. By comparison we have scaled the control points for the contours in Figure 5-ii, again by x 4 and x 8 and rendered these as in Figures 5-iv and -vi where we can see that more detail has been carried into Figure 5 -vi than in Figure 5 -v.

For our second application we chose a different kind of operation, histogram equalisation. The purpose behind histogram equalisation is to adjust pixel values so that each sub-region of the image yields equal energy. Properly histogram-equalised images should show the highest contrast everywhere in the image and this is supported by a rectangular histogram across the range, particularly for the Y component of a YUV image. Unfortunately pixelbased histogram equalisation usually only manages to achieve the sort of result in Figure 6-i. The diffusion interpolating technique however does not require level lines to be associated with integral values although one might start out that way. Instead one could determine what level values would give the nearest to a rectangular histogram. The neatest way of doing this would be to start off with contours of values which vary in powers of 2 from 127, i.e. 127, 63, 191, 31, 47, 159, 223 etc. The 127 contour should partition the image area exactly in half and if not, its value needs to be reassigned to whichever contour comes closest to achieving that partition.

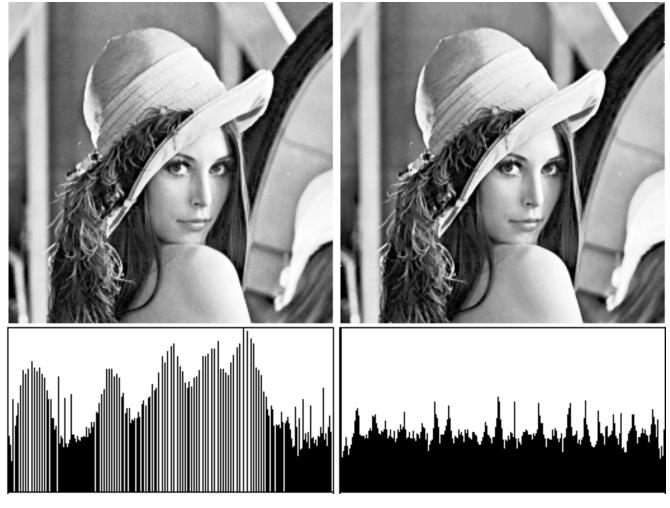

Figure 6 (i) histogram equalized by pixel reassignment

(ii) same by level reassignment

We note that if the 127 level covers exactly half the image area then the 63 contour should cover half of that half (and the 191 level covers half of the other half plus a half) etc. In other words each level I can be re-assigned according to the proportion of pixels that the contour footprint should cover, e.g. as assigned by a 1:1 mapping H(I). We reassign the levels by indexing the inverse function $H^{-1}()$ by the proportion P0 of pixels actually covered ($0 \le P \le 1$). Here $P(I) = 2^{\ln(I+1)-8}$ so $P(I) = P \cdot 2^8 - 1$ (for an 8-bit per primary quantised colour space).

Figure 6 shows the results of performing histogram equalisation in this way. Here the first row shows the resultant images and the second row shows the corresponding histograms. It is clear that the right hand image Figure 6 (ii) has the strongest contrast enhancement of the two images and in particular lacks the artefacts of the left image Figure 7(i) which are in the main caused by the gaps introduced by pixel reassignment in the histogram.

6. Conclusions

Vector formats for photographic images have been studied for various purposes since the mid 1970s and there are broadly two approaches, the morphological approach which in effect requires every individual quantisation of the colour level to be represented, and the topological approach which attempts to model the isosurface as economically as possible. Level sets, as we have used them here, are a bridge between the two approaches and can benefit from results in either. Many image manipulation operations on this form are both simpler and seem to give better results (as here, warping and histogram equalisation) than their raster equivalents. One kind of transformation is particularly straightforward, that of varying the colour depth resolution in the resulting image. This is because the final samples for the observed image are calculated as a convolution of samples into the continuous field and these need then to be quantised to whatever colour depth is required. Thus the vector form is independent both of spatial and colour depth resolutions in the original input.

However there are residual problems with the vector approach which can be summarised in terms of conversion speed and file size. Conversion times in and out of the vector format are approximately linear with input image size although it is known that images with a lot of high frequency detail take longer to encode and decode than images with a more usual distribution of frequencies. For example the 'mandrill' image (another one of the standard test set) takes twice as long to encode as 'Lena'. On a 500MHz PC 'Lena' at 256x257 took 15 seconds to encode and 20 seconds to decode, but this is without any graphics acceleration assist. The codec is (by intention) well-suited to streaming and parallelisation. Our view is that, given the

degree of support available for graphics processes, these times will be significantly improved in practice. On the other hand the fixed contour level setting strategy resulted in file sizes 10x larger than their pixel equivalents which we did not attempt to address in the work being reported here. However, the results of Lindeberg [1998] suggest we have been far too conservative in fixing the local resolution of contour segments in smooth areas. If we compute a resolution measure which scales with local smoothness we should be able to significantly reduce the number of segments per contour. We have also (knowingly) been far too conservative in the numbers of contours we find, possibly by as much as a factor of 20, but it will take a (much more complex) adaptive encoder to find the local optima. Compression is an obvious focus for future work.

Our original concern was to be able to reproduce photographic images from contour form so that they looked visually indistinguishable from the original. In this we were generally successful. Reliably better results could be obtained with an adaptive encoder which starts as we have done here by encoding contour 127 then splitting the intervals on either side etc. Such an adaptive encoder (e.g. Patt& [2006]) would maintain a test render and only split an interval further if the pre-render resulted in pixel values falling outside the assumed error bounds around the original pixels. Where this condition happened locally, a local decision to subdivide further could be taken. We estimate that such a codec would take twice as long to encode than our fixed-level encoder. It would take considerably less time to decode, although this time would be more image-dependent than before. File size should be significantly improved also. The gains here also depend on the noise-estimation method used as well as the extent to which the diffusion process mimics the expected variation of pixels values within a contour footprint. Here there are a number of possible improvements to be made.

The main improvement is to use a standard level set approach [18] of adding or subtracting (depending on the sign convention used) the traversal speed of the level line with a (usually) small amount, calculated as (say) 0.01 x curvature, where curvature is calculated as $\nabla \cdot \frac{\nabla \Psi}{|\nabla \Psi|}$. This

has the effect of smoothing out 'shocks' or discontinuities in the evolving line, which is a common problem in interpolating systems [15]. (We note also that loops are another problem with 2D interpolators but the rules for interpreting Level Set solutions explicitly precludes these under the 'weakest solution' rule; instead the loop is cut off at a point which often leaves a visible shock.) Shocks also arise when two advancing fronts intersect one another but again the 'weakest solution' [18] applies to determine a single front. Again the foregoing modification smoothes away the discontinuities, but the calculated indices are no longer computed from wholly linear (Euclidean) distance

values. It is also possible to manipulate these indices further so that tangents in the trajectories of index values are matched across contour boundaries to achieve G¹ continuity (C¹ can be achieved with greater difficulty, typically as a post-process if needed after establishing G¹). While we would expect an improvement in image quality (and a matching improvement in file size) by these measures, such improvements are usually visually unnoticeable in an unwarped image.

Our motivation for this work has been based on the intuition that contours will commonly follow the features of objects in the image. We hope in the future to be able to show that 'difficult' operations like matte-pulling and holefilling will be enhanced by vector formats in addition to the processes whose enhancement we have already demonstrated. Image re-sizing is such an example where the vector format can be exploited to define localised warps aimed at preserving the slope angle at edges. This has the effect of retaining feature sharpness but vector image resizing under various regimes is potentially the subject of an entire paper in itself, so, despite its importance to some industries, this has not been discussed here. What we have shown already is that there is a viable continuous image format and that it can be used for some conventional operations which are not handled easily in sampled formats. Moreover, while the representation cannot reveal more detail than in the original sampled image, it does offer a robust model of that image, with all the advantages of being able to render it at different qualities for different devices. It thus has the advantages that SVG offers for graphical pictures but with the ability to deliver the full quality of photographically-captured images.

Acknowledgements

We acknowledge funding from the Scottish Enterprise Proof-of-Concept Plus programme and wish especially to acknowledge the work of Peter Balch (Analogue Information Systems Ltd) who implemented the code from which the examples to this paper were produced. We thank the referees for their helpful comments.
